Liver cells and striated muscles also represent a very high differentiation. It is possible that with more exact knowledge we shall be able to state that these elements also cannot produce tumors, although there may be tumors of the liver and of striated muscle fibres. Possible, because Cohnheim's famous theory of tumor origin from persistent embryonic tissue may be, though not generally applicable, yet available in these two instances. The adoption of this view would furnish an explanation of several familiar facts: of the fact that we do not find tumors formed by differentiated liver cells; of the fact that cancer of the liver arises usually from the bile ducts, which have a simple and little differentiated epithelium; of the fact that myoma of the cardiac and of the developed skeletal muscles is exceedingly rare; of the fact that rhabdomyomas so occur that their origin may be attributed to inclusions of portions of embryonic muscle plates. As regards primary epithelioma of the liver, it is claimed that it arises usually from the bile ducts, but the liver cells are also involved, but how it comes about that the liver cells participate is, so far as I have been able to learn, by no means clear. From analogy with other tissues, we infer that it is improbable that the large and specialized liver cells ever resume an embryonic character. In short, I deem our understanding of the pathological differentiation of hepatic cells and of striated muscle fibres too imperfect to support a judgment. We can only say that the rarity of such differentiation concords with the degree of normal specialization of the cells and fibres in question.

Our very brief discussion of pathological differentiation seems to justify the following conclusions: (1) The process in its essential features is identical with the process of normal differentiation; (2) the character of a tumor depends primarily upon the layership of the cells producing it; (3) normal differentiation impedes and limits the formation of tumors, precisely as it does of further normal structures, so that tumors arise most readily from undifferentiated tissues and may then be heteroplastic; arise less readily from differentiated tissues and are then always homoplastic; and arise unreadily or not at all from the most highly specialized tissues. Each of these three conclusions might be advanced as a law of normal development, if we substitute the term "differentiated tissue" for "tumor."

We now pass on to the final stages of cytomorphosis, necrobiosis and hypertrophic degeneration in their pathological manifestations. The consideration of the direct or simple death of cells need not detain us, nor need we pause long over the indirect forms of cell death. In fact, the analysis made earlier this evening, of normal necrobiosis and degeneration, forced us to recognize that all, or nearly all, the modes of indirect cell death which the pathologist encounters in morbid tissue recur under healthy normal conditions. To put the conclusion in its correct form, we need only to reverse it, saying: Most, and probably all, pathological necrobiosis and degenerations of cells are essentially identical with normal processes, and are pathological owing to the abnormality of their occurrence in time and site.

Death of a cell may, of course, occur at any moment as a consequence of conditions external to itself. To a given cell, as such, it is of no moment whether the term, "physiological" or "pathological" be applied by us to the conditions which cause its death. The cell has its own inherent qualities, and its own cytomorphic possibilities. All that the environment of the cell can do, so far as we can at present understand, is to evoke, and perhaps to a minor degree modify, one of the possible structural changes of the cell. Hence we find actually that the processes of cellular necrobiosis appear to us identical in normal and pathological cases. This affirmation does not imply that a given cell has only one kind of possible necrobiosis before it. Quite otherwise, it being reasonable to believe that any one of several forms of necrobiosis, according to the circumstances, may ensue.

All that has just been said might be repeated in reference to hypertrophic degeneration. One of the investigations which is most needed at the present time, and which promises results of extreme interest and importance, is the investigation of necrobiotic and degenerative cytomorphosis, carried out as a research upon cell structures. At present we cannot discuss the subject except

in terms the very vagueness of which is a mortifying confession of ignorance.

Time forbids the prolongation of the discussion. But, although a more detailed study is thus for the present excluded, we have, nevertheless, dealt with the subject with sufficient fullness, I hope, to convince you, if you were not already convinced, that the fundamental problems of pathology and embryology are alike, not only in being problems of cell life, but also in being similar and even identical problems of cell life. Widely as the two sciences differ, they rest on a common foundation.

To complete our subject it would be necessary to summarize our present knowledge as to the causes of cell differentiation. Physiological morphology is a new science; we have barely crossed its threshhold, and are not yet at home in it. To the physician this new science promises to far surpass in practical importance even the bacteriology of our time, since it is not presumptuous to hope that when we understand the physiological factors, thermal, chemical stimulant, mechanical and other, which bring about structure, which cause cytomorphosis — that then we can acquire control over cellular differentiation, and ultimately be able to prevent some of the most formidable diseases, over which we now have little or no power. The diseases which we may attack in the future, in this way, are diseases which may be designated as morphogenetic, because they are due to errors of morphological differentiation. At this vast topic it is quite impossible now to more than hint.

Here we may stop, not because all the great host of relations between embryology and pathology have been marshalled before us, but because enough of those relations have passed us in review to present a conclusive body of arguments. As we follow their march, we find ourselves led to the attack upon the problem of the causes of the specialization of cells, of histogenesis. To conquer this problem our only hope lies in the junction of all our forces.

Before closing, a personal word: First, of sincere thanks for the honor you have conferred upon me, both by your invitation and by your attention, and then a word to express the great diffidence with which I have undertaken to deal with pathological phenomena. A man of science ranks according to the number of details which he has mastered, and his ability to drill them into coherent battalions. By no such system of ranking can I hope to be included among pathologists. I offer, therefore, only the thoughts of an outsider, derived from the long pursuit of a cognate science. Such external suggestions, being independent to some degree of pathological tradition, may contribute to vivify the conception of the unity of the biological phenomena, and, therefore, of all forms of biological investigation. It will be a service rendered if my words recall the great truth that biology is not a congery of sciences, but a single science, which we artificially divide and sub-divide until the parts are commensurate with our mental capacity. In the truest sense we are fellow-workers. Let us, therefore, work together.

A NEW METHOD OF TREATING FRACTURES.[1]

BY LEONARD F. HATCH, M.D., LYNN, MASS.

When one stops to think of the rapid advance made in surgery during the past fifteen years, it seems little short of marvellous, and as though the wand of a magician had touched the art and shorn it of its crude and uncertain ways, and transformed it into the nearest approach to an exact science that we have in the whole field of the physician. Is it not remarkable that we have applied none of these new principles to the treatment of fractures? They are treated in the same indefinite and unscientific way that they were fifteen years ago, and have received none of the advantages of our recently acquired knowledge. The x-ray certainly has been brought to bear upon this field, but it is of comparatively little value. Does it show us the spiculæ of bone sticking into the soft parts? Does it show the fold of soft tissue caught between the two ends? Does it show the blood clots, the loose particles, and the ragged tissues that nature must take care of before union can commence? Does it obviate or tend to prevent in one particular the danger of non-union? I would not detract from the value of the x-ray, but merely contend that in the field of fractures it is of far more interest to the surgeon than of practical benefit to the patient.

Striving to establish a new method for the treatment of fractures, based on modern surgery, I have been severely hampered in applying and practically testing it by a lack of material, as it is very hard to get patients to permit a departure from established lines, and then, too, one has to be very sure of his theory before making a practical application of it, but I have been able to persuade a number to permit me to make use of it.

The principle (a part of it old but not followed generally, the other never having been used or advanced, to my knowledge) is to convert all compound fractures into simple ones; the other is to operate on simple fractures, making them compound, and then apply the first principle, making them simple.

I would submit a few cases bearing out these principles. I have had 6 cases of compound fracture of the large bones, besides a number of the small bones, which I have treated by making simple. I have operated on 4 simple fractures of the long bones and 5 fractures of the patella. All of these cases have given perfect results, without a drop of pus or any apparent inflammatory action. I have used drainage only once, and that was in the case of a compound fracture of the thigh. Fractures treated by this operative method are

[1] Read before the Lynn Medical Society, February 20, 1900.

practically devoid of pain. The sharp spiculæ of bone sticking into the soft parts and the swelling are the principle causes of pain, and both of these are avoided by the operation.

Technique of operation is the same for simple and compound fractures, with this exception, that in simple fracture there is a point of selection for the incision, while in a compound fracture the wound is simply enlarged. There must be the most perfect antiseptic preparation. The site of operation must be shaved and then scrubbed thoroughly with soap and water, bichloride solution, and permanganate and oxalic acid solutions; all other parts of the patient must be carefully covered with sterile sheets and towels. Hold the extremity in a vertical position for a few minutes, then apply a rubber constrictor. Fit a sterile posterior and anterior splint of any suitable material. The points of selection for incision are for the tibia along the crest, for the femur along the outer side of the thigh, for the radius behind the supinator longus, for the ulna along the ulnar side of the arm where the bone is most superficial, for the humerus along the outer side of the arm. A good, free incision should be made, as it is important to have plenty of room, and the size of the incision does not complicate the case. Wash out thoroughly all clots and débris, removing all shreds of soft tissue and loose pieces of bone. If any sharp points of bone prevent perfect coaptation, remove them. Remove rubber band. Tie all bleeding points, and be sure that the wound is dry. If in case of a compound fracture the periosteum is stripped up, carefully replace it. Secure perfect coaptation. Apply one of the splints before closing the wound, to make sure of holding the fragments in place. Close the wound with catgut sutures without drainage, and lay a thin pad of iodoform gauze over the wound; apply the second splint and bandage quite firmly, as there will not be any swelling like that which occurs after a fracture treated in the usual manner. Remove dressings on the seventh or eighth day and apply plaster cast or ambulatory splint, according to the requirements of the case. It is safe to discontinue splints at least one week earlier than in fractures treated by former methods.

CASE I. Mr. D. age forty-eight, weight 150 pounds, height 5 feet and 11 inches; general health good. In breaking a colt was thrown out and dragged a long distance, resulting in a compound fracture of the radius. Enlarged the opening and washed out bloodclots, etc. Found some difficulty in reducing fracture, but after removing a few spiculæ of bone it came together nicely. Closed wound without drainage. Removed dressings on sixth day and found a union of soft parts complete without pus. Applied plaster cast, which was removed on the twenty-fourth day. Union complete. No deformity.

CASE II. Mr. T. age forty-four, weight 180 pounds; general health good; truckman. In unloading a heavy desk slipped and fell, the desk falling upon his leg, causing a compound fracture of tibia. Made a good, free opening, and after cleansing out wound thoroughly, and securing perfect coaptation of fragments, I closed the wound without drainage. Dressings removed on seventh day, and found perfect union without pus. Applied ambulatory splint, which was removed on the thirtieth day. Union perfect, with no deformity.

CASE III. Mr. B, age forty, weight 230 pounds, height 5 feet and 10 1-2 inches; a hard drinker. Tipped over with a load of furniture, sustaining a compound fracture of the thigh at the middle, the bone protruding posteriorly. Enlarged the opening and cleansed the wound with a bichloride solution. Reduced the fracture and closed the wound, leaving silk drainage, as there was quite a little exudate. Applied splints with weight and pulley. Removed drainage without removing dressings at the end of twenty-four hours. Removed dressings on the eighth day; no pus; removed sutures. Recovery uneventful; there was no shortening. Dr. Bennett, who saw the case with me, advised amputation, and expressed the opinion that it was foolhardy to close up the wound.

CASE IV. Mr. J, age fifty, weight 145 pounds, height 5 feet and 10 inches; keeps a variety store. While putting up some flags on the top of a veranda for a Fourth of July celebration, fell to the ground, causing a compound fracture of the tibia. Enlarged the opening and cleaned out the wound thoroughly. After perfect reduction of fracture, closed wound without drainage. Dressings removed on seventh day, and found union of soft parts without pus. Applied ambulatory splint, which was removed at end of fourth week. Union complete, and no deformity.

CASE V. Mr. R., age fifty-two, weight 257 pounds, height 5 feet and 11 inches; foreman of the Lynn Water Works, was in a ditch when a heavy derrick fell on him, causing a compound fracture of the tibia and fibula of the right leg at the junction of the middle and lower thirds. The tibia penetrated his trousers and overalls, and was forced into the gravel. I enlarged the opening without an anesthetic, as the patient refused to take one, and cleansed the wound and the bone very carefully with bichloride solution, then carefully replacing the periosteum, which had been stripped up, I reduced the fracture, being sure of perfect apposition, and closed the wound without drainage. Removed the dressings on the seventh day; no pus, union of soft parts. Further recovery was uneventful. Union complete at end of fourth week; no deformity.

CASE VI. Mrs. B., age thirty-two, weight 145 pounds, height 5 feet and 8 inches; general health good. I operated on this case three years ago for double salpingitis. She was thrown from a carriage in a runaway accident at Wells Beach, Maine, striking a telegraph pole and sustaining a compound fracture of the radius and ulna at lower end — practically a Colles fracture — and was badly bruised about the face and shoulder. It was after midnight when I arrived. The patient had been attended by a local physician in the morning at the time of the accident, and the arm put in a

splint. She was suffering severe pain at the seat of fracture. On examination under ether, I found that the fracture was not properly reduced, and that the skin was still between the fractured ends of the radius. Through a free incision I cleansed out the wound thoroughly, and after securing perfect coaptation closed the wound without drainage. Removed dressings on eighth day and found soft parts united; no pus. Applied plaster cast. Removed cast on eighteenth day, and commenced passive movement of fingers. Considered union of fracture complete on twenty-fifth day; no deformity, and recovered perfect use of fingers and hand.

CASE VII. Mr. M., age twenty-nine, weight 160 pounds, height 5 feet and 10½ inches; strong, muscular man, grocery clerk, when getting down from his team with a basket under each arm, fell on the ice, causing a fracture of the left tibia, at the junction of the middle and lower third. After preparing the patient for operation, I first reduced the fracture in the usual way, that I might determine how perfectly fractures are reduced by the old method. Before cutting down upon it it seemed as though I had complete apposition, but I found it to be only approximate, as there was nearly a half-inch separation. It was filled with blood clots and loose fragments of bone, one sharp spiculum of which was sticking into the soleus muscle. I cleansed it out thoroughly, secured perfect coaptation, and then closed the wound. Dressings removed on the eighth day; no pus; applied ambulatory splint. Recovery was uneventful; splint removed on twenty-fifth day.

CASE VIII. Mr. S., age thirty-four, weight 150 pounds; fair general health. Sustained a fracture of the humerus at the middle third. After the usual preparation for operation I tried to reduce the fracture but could not do so satisfactorily without using more force than was desirable, as I wished to find out what the true nature of the difficulty was. On cutting down upon the fracture I found the usual quantity of clotted blood and débris, and a good sized spiculum of bone at a sharp angle to one surface in the direction of the other. Upon cleansing out the wound and removing the fragments the fracture came together perfectly. I then closed up the wound in the usual manner. Recovery perfect and uneventful.

CASE IX. Mr. K., age twenty-eight, weight 140 pounds, height 5 feet and 9 inches; machinist. Was thrown from a carriage, striking the curbstone and sustaining a fracture of the thigh at junction of lower and middle thirds. Operated by cutting down upon the fracture, removing blood clots and loose particles of bone, secured perfect coaptation, and closed the opening without drainage. Applied splints with weight and pulley. Removed dressings on the seventh day. Union of soft parts, no pus. Union perfect, with no shortening, at end of fourth week.

CASE X. Mr. D., age thirty-eight, weight 160 pounds, height 5 feet and 10½ inches; general health good; clerk. While standing on a barrel to fix some batteries, fell, fracturing the humerus below the insertion of the deltoid. Operated, removing blood clots, etc., and after securing perfect coaptation, closed the wound and applied splints. Removed dressings on the eighth day. Union of soft parts without pus. Applied plaster cast, which was removed on twenty-fifth day. Union perfect.

I will give in detail one case of fractured patella only, as the other cases pursued the same course, and recoveries in each one have been perfect.

CASE XI. Mr. L., age eighteen, weight 160 pounds, height 5 feet and 10 inches; very muscular; a grocery clerk. Fell down stairs and fractured the right patella. I saw him on the fifth day with the attending physician, Dr. Parcher, and advised an operation, which was consented to. On the tenth day I operated under the best aseptic conditions possible with the existing surroundings. I cut down upon the fracture and found the joint filled with clotted blood. There was a single transverse fracture of the patella. The capsular ligament and the accessory bands of vastus were torn apart and the edges very dark and ragged. I think a fractured patella presents the most formidable sight that the surgeon has to deal with outside of the abdominal cavity. It is a thing that must be seen to be appreciated, and I would advise any one to be very sure of his surgical ability before attempting it. I cleansed the joint out thoroughly and trimmed off the edges of the torn ligaments. I had planned to use heavy kangaroo tendon, but when I came to use it, it was so rotten that I had to abandon it and use heavy silk. I passed the needle through the ligamentum patellæ close to the patella, then through the conjoined tendon close to the upper fragment, and after securing perfect apposition, tied the silk, which held them perfectly. I then put a few stitches of catgut in the capsular ligament and closed the wound. The patient did not suffer nearly so much pain after the operation as he did before. I prefer this method to that of drilling the bone. By means of an apparatus which I designed, I kept the leg elevated at an angle of 45° for eight days. On the eighth day I dressed the wound for the first time. It was healthy; no pus or swelling. I then removed the stitches and applied an ambulatory splint, permitting the patient to be up about the room. Discharged the case at the end of the fourth week. At the end of the fifth week Dr. Parcher brought him to my office, and he had no trouble in walking from the depot to the office. At that time, while lying flat upon the back, he could raise the leg to a perpendicular position without the slightest bending of the knee. Motion in the knee was very good at this time, but two weeks later was perfect. In walking there was absolutely no throwing ahead of the leg, as is usual with cases treated by any other method. On examination it was almost impossible to find the point of fracture. Three of the other cases have

NOTE.—Mr. L. was examined by over fifty members at the medical meeting, Dr. Parcher kindly taking him around to each one, and there was not one of them who could locate the place of fracture, which I think proves the result.

been treated by this method, that is, making use of the ambulatory splint with equally good results.

CASE XII. Mr. M., age fifty-eight, weight 145 pounds, height 5 feet and 11½ inches; good health; builder. Fell forward in getting down from a wagon, fracturing the right patella. Operated at once; applied ambulatory splint on eighth day. Recovery uneventful, and case discharged at end of fifth week.

CASE XIII. Mr. F., age sixty-two, weight 140 pounds, height 5 feet and 10 inches; good health; no occupation. Fell on a car track, fracturing the left patella. Operated on ninth day; applied ambulatory splint on ninth day after the operation. Recovery uneventful at end of fifth week.

CASE XIV. Mr. N., age thirty-eight, weight 150 pounds, height 5 feet and 10 inches; teamster. In jumping from moving train, fell, fracturing both patellas. He was intoxicated at the time. Operated on the ninth day. Kept patient in bed five weeks. Recovery perfect.

CASE XV. Mr. R., age forty, weight 130 pounds, height 5 feet and 9½ inches; good health. Fell from a step ladder, fracturing left patella. Operated on ninth day. Applied ambulatory splint on eighth day following operation. Recovery uneventful, and perfect results.

All of these cases of fractured patellæ have given perfect results, and there is absolutely no throwing ahead of the leg, as is usual in cases of fractured patellæ treated by other methods, and resulting in union by a fibrous band with greater or less separation of fragments.

Deductions.— (1) With the advance made in modern surgery, where we do not hesitate to enter the abdominal or cranial cavities (in some cases, even, simply to establish a diagnosis), we surely should not be deterred from operating on fractures by fear of sepsis, and it certainly is unscientific to adopt a blind way when a better presents.

(2) It would be warranted if it did nothing more than to relieve the pain and swelling, which it certainly does.

(3) It shortens the repair process at least one week.

(4) It reduces the chances of deformity and non-union to a minimum.

I consider the ambulatory splint the best dressing for fractures of the leg, as it permits the patient to be up and about, thus avoiding the usual loss of strength, and enabling a great many to attend to portions of their business. In one case where I used the ambulatory splint for a fracture of the tibia, the patient, who owned a grocery and provision store, was enabled to go to the store daily, and to Boston once a week to attend to the buying.

A NEGRO CENTENARIAN. — James Garrison, a negro and former slave, died on March 16th at Richmond Terrace, Staten Island, at an extreme age, commonly reported in the neighborhood as one hundred and twenty-five years, though this is doubtless a considerable exaggeration.

Clinical Department.

MUMPS IN PNEUMONIA; BOROGLYCERIDE.

BY CHARLES W. DULLES, M.D., PHILADELPHIA, PA.

IT is a curious but well-known fact that at certain times there occur almost simultaneously a considerable number of cases of forms of disease or injury which are in general quite rare. This has been recently illustrated by the publication by several observers of reports of the development of mumps in the course of pneumonia. The articles in which these cases have been recorded indicate that insufficient mention of this complication, in the text-books, has led to the impression that it is more rare than it actually is. As a matter of fact the occurrence of inflammatory swelling of the salivary glands in the course of pneumonia is spoken of in such really comprehensive works as that of Wilson Fox on "Diseases of the Lungs and Pleura." Still, the publication of recent observations is more likely to put the members of the profession on their guard than its mention in the books. For this reason — and for another — I think it worth while to make public an observation of my own occurring during the winter of 1899–1900. My patient was a woman over eighty years of age, living in a home for aged women in this city, a person of great neatness and careful habits, who contracted a cold and passed at once into a croupous pneumonia affecting the left lung. She became very ill, but after the crisis she began to improve, and eventually she fully recovered. Just after the crisis I found that she had marked swelling of the right parotid gland which presented all the characteristics of mumps; and afterwards the left parotid gland went through precisely the same stages. In this case there was no question of a second infection from without; it was a plain case of autoinfection.

The second motive for this publication, referred to above, is to describe the treatment adopted. On each side successively I applied a fairly thick compress of surgical gauze saturated with boroglyceride and covered with a layer of paraffine paper and just enough bandage to keep it in place. The relief of pain and the subsidence of swelling which promptly followed the application I am disposed to attribute to the boroglyceride. This is an application of the greatest utility in a variety of inflammatory swellings, and especially in the case of incipient boils and carbuncles. In my hands it has wholly replaced the poultice; and since some years ago, when I began to use it where poultices used to be employed, I have not had to apply the knife to either boil or carbuncle. I have also found it useful in inflammatory swellings below but near to the true skin. I have observed recently the extensive advertisement of a special preparation recommended for use in similar cases, which I am informed consists of a mixture of gylcerine and talcum powder. If this has proved of value, I believe that it was through the depleting influence of the glycerine; and boroglycer-

ide — of a strength not greater than 50% — I presume would be a more rational and equally useful application.

A BRIEF SUMMARY OF NINE CASES OF LOBAR PNEUMONIA TREATED BY ICE PACK.

BY GEORGE L. COLLINS, M. D.,

House Officer, Carney Hospital.

Having in mind the discussion of the treatment of pneumonia in the *Medical Communications of the Massachusetts Medical Society*, Vol. XVIII, it was deemed advisable in the last service of Dr. Wm. F. Temple, at the Carney Hospital, to try the effect of treatment of lobar pneumonia by the continued application of dry cold over the seat of the pulmonary lesion. The cases reported below came under my direct charge during this service. The treatment adopted consisted in the conventional supportive and symptomatic treatment plus the application of dry cold by means of ice-bags.

Case I. M. H., age sixty-five. Comes in with temperature of 102°, pulse 100, respirations 40. Second day of attack: Pain in left lower chest; cough. Bronchial breathing, prolonged expiration and few fine crepitant râles at left base. Lungs otherwise negative. White count, 21,000. Treatment: Liquid diet, whiskey half ounce every three hours; strychnia, one-sixtieth grain every four hours. Left chest packed with ice-bags below. In one day temperature reached 103.6, and two days later (fifth day of disease) the temperature, pulse and respirations were normal. Signs in chest never showed any increase; never any dullness. Râles cleared up on fifteenth day. This patient was the only one of 9 cases to complain of discomfort of ice-bags. Discharged well on 18th day of disease.

Case II. C. F., age twenty-three. Comes in on second day of attack. Cough; pain in neck, chest and abdomen, bloody sputum, anorexia, vomiting. Heart enlarged, no murmurs, pulse regular. Expansion of chest limited on left side; left lower lobe shows usual signs of consolidation; only few râles in right chest. Temperature 103°, pulse 120, respirations 46; white count 52,000; urine normal. Treatment: Strychnia, rum, ice pack to left chest. Two days later (fourth day of attack) temperature fell to 99.2°, reached normal a week later. Ice pack omitted on eleventh day of attack. Signs cleared up on fifteenth day. (See diagram.)

Case III. M. S., age sixteen. Entered on third day of attack. Headache; pain in chest, aggravated by cough and deep inspiration. No expectoration of any account. On entrance nothing found in chest but weak breathing in lower left chest; face flushed, temperature 102.3°; white count 46,000; urine normal with chlorides diminished. Left chest packed with ice about the base on the chances. Two days later (fifth day of attack) distinct and marked signs of consolidation in upper right lobe. Temperature on this day 103°. Ice pack at once changed to this side, and rum and strychnia continued as from entrance. Temperature dropped on this day. Reached normal on eighth day of disease. On thirteenth day of attack dullness almost all cleared up; râles on coughing; slight pleuritic pain in lower right chest. Signs cleared up on seventeenth day. (See diagram.)

Case IV. M. M., age seven. Entered on third day of attack. Temperature 104°, pulse 130, respirations 40. Pain in left chest, cough; no expectoration, headache, anorexia, constipation, some abdominal pain. Usual signs of dullness, with no râles in left lower lobe. White count, 50,000. Active hyperemia of kidney. Treatment: Whiskey, liquids, strychnia, left lower chest packed in ice. One day later (fourth day of disease) temperature began to fall, and was normal on sixth day. Signs cleared up on fourteenth day.

Case V. D. M., age sixty. Entered on second day of attack. Cough; dyspnea; slight expectoration, not bloody; constipated; pain in chest; cheeks flushed; white count 10,000; temperature 101°. Treatment: Whiskey, strychnia, ice pack to left chest, where dullness with bronchial breathing and râles were found. Three days later distinct consolidation of right middle lobe with usual signs appeared, with friction rub over lower right lobe. White count 13,000. Left chest now clear. Ice pack changed to right side of chest. Pulse now intermittent. Temperature still about 101°. Two days later (seventh day of attack) temperature rose to 102°, pulse 100, irregular and intermittent, respirations 50. One day later, signs remaining unchanged, patient died.

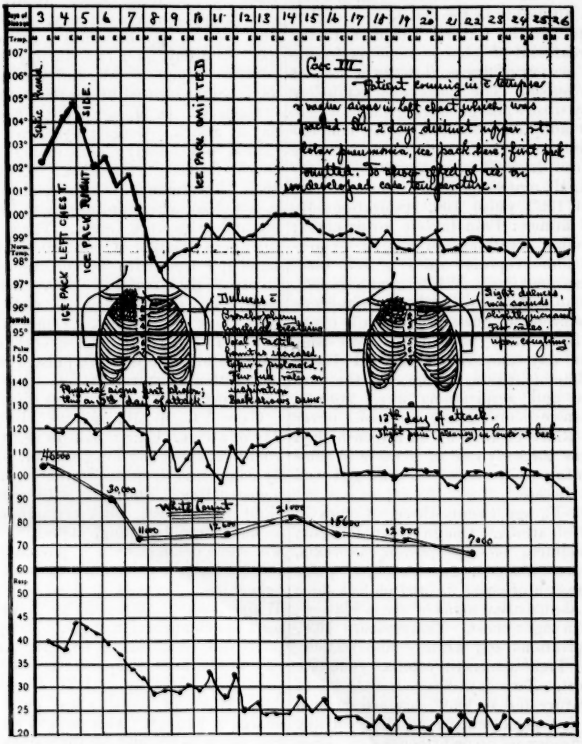
Case VI. M. M., age 28. Entered on third day of attack. Chill; pain in right side of chest; vomiting, expectoration greenish; pain made worse by cough and deep inspiration; constipated; now menstruating. Dullness with usual signs over right upper lobe, râles throughout either chest, — moist and bubbling. Question arose whether we were dealing with a pneumonia in state of resolution, or a pneumonia on top of a generalized bronchitis. Ice pack decided on; rum, strychnia. White count 52,000; active hyperemia of kidneys; pneumococci in sputa. Temperature 103.5°, pulse 120; respirations 58. In three days (sixth day of disease) temperature fell to normal, and process in right upper lobe cleared up on tenth day. Râles in either chest persisted until discharge of patient. This patient was exceptionally sick on entrance and for three days after entrance, but she never complained of inconvenience from ice pack. Ice pack was left on six days and removed on ninth day of attack.

Case VII. C. H., age thirty-eight. Comes in in state of delirium tremens. On spree four days. Dullness with usual signs found in lower left lobe. As near as can be made out this is fourth day of attack. Dyspnea, cough; pain in lower left chest, made worse by cough or deep inspiration. No blood in expectoration. Temperature 103°; white count 17,300. Treatment: Calomel, followed by salts; bromides, chloral, capsicum; ice bags to

left lower chest, whiskey, strychnia. In twenty-four hours temperature fell to about normal (fifth day of attack). Signs in chest practically all gone on twentieth day.

CASE VIII. G. S., age eleven. Entered on second day of attack. No chill; cough, pain in right chest, no expectoration; dullness with usual signs over right upper lobe. Chlorides in urine diminished; white count 23,000; temperature 105°; pulse 123, of poor volume and compressible; respirations 50. Treatment: Rum, strychnia, ice pack to affected lobe. In three days (fourth day of attack) temperature dropped to normal, and white count dropped to 16,600. On sixth day ice omitted. Signs cleared up by fourteenth day.

CASE IX. G. B., age fourteen. Entered on third day of attack. Pain in right back, vomiting, cough; pain made worse by cough; rusty expectoration. Temperature 103°, pulse 110, respiration 30. Physical examination shows dullness with usual signs over middle lobe, especially in back. White count 34,400. Treatment: Rum, strychnia, ice pack to right chest. Temperature fell on fifth day of attack. Lungs showed only an occasional râle on ninth day.



SUMMARY AND CONCLUSIONS.

In only one case did the ice pack cause discomfort. In no case was the crisis accompanied by dangerous collapse.

The pack has been used to abort cases just beginning (Case I), in cases with well marked signs, and in cases showing resolution.

Contemporary signs of bronchitis were not considered contra-indicatory.

High temperature (and not physical signs) has been in each case the indication for application of ice. Lowered temperature and not physical signs has been in each case the indication for removal of ice. The average fall in temperature was 4.5°. In all but one case this fall was within forty-eight hours of application of ice. In most cases it was within twenty-four hours. The slowest fall of temperature following ice pack was in Case III, when temperature took five days to fall 7°. This patient was suffering from a septic hand. The

average fall of temperature was 4.5° and took place on the fourth day.

The white count invariably began to fall with the temperature, but reached normal in no less than one week after temperature was normal.

The ice pack apparently had no particular effect in either shortening or prolonging the duration of physical signs. The physical signs cleared up on the fourteenth day.

Medical Progress.

RECENT PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

THE MANAGEMENT AND CONTROL OF INFECTIOUS DISEASES.

The Utility of Isolation Hospitals in Diminishing the Spread of Scarlet Fever.

Attempts having been made in England to show that isolation hospitals had failed to accomplish the object for which they were intended, Dr. Newsholme[1] contributes a paper in which he shows that, if death rates are to be considered as conclusive, the returns relating to scarlatina "show a strong case for the continued use of the present preventive measures, among which hospital isolation and disinfection claim an important part." He shows that in the period 1850 to 1885 the death rate had been extremely irregular, rising frequently to a very high rate and then sinking to a very low one, as, for example, from 451 per million in 1861 to 1478 per million in 1863, and down again to 546 in 1866. But since 1885 the mean rate had not only been low, but it had been quite uniform and free from extremes from that time to the present. He concludes that "preventive measures, among which hospital isolation holds an important place, have been associated with the remarkable and almost uninterrupted decline in the death rate from this disease."

The reasons which he assigns for the fact that an ideal condition has not yet been attained are briefly the following:

(1) Hospital and home isolation have never been perfectly carried out.

(2) Not only have a considerable proportion of the notified cases remained unisolated, but a considerable proportion of the total cases have not been notified. This is due to various causes, such as failure to call in medical aid in slight or unrecognized cases, errors in diagnosis and neglect to notify. Every additional case notified gives an additional opportunity for preventing the spread of the disease by personal infection; and every such notified case can be made a centre of inquiry leading to the detection of unnotified cases, if sanitary administration be active and intelligent.

(3) The best sanitary administration cannot accomplish everything. There must be hearty co-operation on the part of parents and medical practitioners, if efforts to secure early diagnosis and early isolation are to be successful. The law is much more regardful of the welfare of cattle than of human beings. A doctor is not required to notify a case of scarlet fever till he "becomes aware" that it is certainly of this nature, but a farmer must notify each case, and *each suspected case* of certain cattle diseases.

To suppose that the spread of a disease caused by particulate infective material is not diminished by isolation of infective persons and by destruction of the infective particles, and to suppose further, that the occasional occurrence of "return" cases is more than a small drawback to the good achieved by isolation hospitals, is to strain the facts and to arrive at a conclusion which is contradicted by our general knowledge of the causation of specific febrile diseases.

[1] Journal of Hygiene, vol. 1, No. 1, p. 145, January, 1901.

Duration of Smallpox Immunity at Pekin.

Dr. Matignon,[2] in a communication to the Academy of Medicine, stated the fact that an attack of smallpox in Northern China confers a temporary immunity lasting from seven to nine years. He also says that among Chinese vaccinated children the ratio of success is 79.5% at twelve years of age, 77% at ten years, and 53.3% at eight years, since the majority of children have probably, if not certainly, had smallpox in their early childhood. He has seen 3 positive cases of smallpox occurring a second time in the same person, the victims being two Frenchmen and one Swiss, and while it is proper to take account of the diminution of resistance caused by the fatigue of a long voyage, the severity of the weather, etc., he says the real cause is to be found in the widespread prevalence of smallpox at Pekin. At the beginning of spring, one may see upon the streets everywhere Chinese with their faces and hands covered with variolous crusts in a condition of desquamation, at the same time selling embroidery, trinkets, etc. He urges the importance of revaccination immediately upon arriving in China.

Prevention of Tuberculosis.

Dr. Thompson,[3] of New South Wales, proposes the following measures for the prevention of tuberculosis: (1) Notification and registration of phthisis. Such registration to be confidential; (2) free examination of sputa; (3) disinfection of rooms obligatory after death or removal of consumptive patients; (4) local registrars to notify every death from phthisis to the health authority as soon as received by them; (5) enforcement of good building laws.

Existence of Tuberculosis at Different Ages.

Nägeli[4] found at the Pathological Institute of Zurich, as the result of 500 autopsies, no traces of tubercle in 16 infants under one year old, 12 of whom were new born. From two to five years it is rare, but fatal when it occurs. From five to

[2] La mèd. mod., November 7, 1900, p. 522.
[3] Public Health, January, 1900, p. 248.
[4] Hyg. Rundsch., 2, 1901.

fourteen, one-third of the bodies showed tubercle. From fourteen to eighteen half the cases were tuberculous. From eighteen to thirty nearly every body showed marks of the disease, but in one-fourth healing had occurred. All the bodies over thirty years of age showed alterations due to tubercle, but in the majority of these the healing process was complete, the proportion of "cures" increasing with the age. It would appear that after thirty years' existence every one (in the neighborhood of Zurich) has been more or less successfully attacked by the *bacillus tuberculosis*, but from the fact that not more than one in six or seven dies of the disease, and that most of these are under thirty, one may conclude that the adult body is, as a rule, well able to resist the attack.

Action of Sunlight on Tubercular Sputum.

Jousset[5] records some experiments made in order to determine the vitality of bacillus tuberculosis in sputum, after exposure to direct and to diffused sunlight.

Dried sputum, after four hours' exposure to diffused sunlight, no longer infected guinea pigs, though the same sputum without such exposure was capable of producing typical tuberculosis on inoculation.

Another specimen of sputum, after an exposure of seven hours to diffused sunlight, produced only a localized tubercular ulcer at the seat of inoculation, without any general infection such as was produced by another portion of the same sputum which had not been exposed.

Sputum, the virulence of which had been tested, was rendered innocuous after drying and exposure to direct sunlight for one hour.

The results show that tubercular sputum when dried in sunlight is either harmless, or, at least, has its virulence attenuated by shorter exposure to sunlight than previous experiments had led us to suppose.

Tuberculosis and Marriage.

Professor Massalongo, of Verona,[6] indicates certain measures which, in his opinion, should be taken to prevent the production of tuberculous offspring.

Recognizing the infectious character of tuberculosis, he says that while it may not be practicable under present laws and customs to prevent the marriage of tuberculous persons, it may be possible to take such measures as shall diminish the dangers of such marriages.

He advises the widespread publication of information upon the subject of the danger of marriage of tuberculous persons; as well of extremely early marriages; also the necessity, where such marriages occur, of rendering them sterile; of removing from the domestic fireside the offspring of such marriages as a matter of safety, and of keeping careful watch of such children till they have passed the period of puberty.

Diffusion of the Plague.[7]

Not a year has passed since 1879 in which the plague has not developed in at least one country, and the number of countries invaded has increased, until in 1898 it was prevalent in Arabia, Persia, China, Japan, India, Russia, East Africa and Madagascar.

Destruction of Rats to Prevent the Plague.[8]

Certain French Navigation Companies have offered bounties to their sailors for rats caught on board the ships. The French Government has also taken up the subject: "If dead rats are found on board ships coming from infected countries they are to be examined bacteriologically; if the plague bacillus is found, the cargo and baggage must be disinfected and the dead rats burned."

Extraordinary Measures for Preventing the Plague.[9]

An order was published in Holland, December 28, 1900, prohibiting, (1) the examination of persons or goods for indications of bubonic plague by means of experiments on animals; (2) post-mortem examination of corpses of persons whose death has been due to bubonic plague, or who are suspected of having the disease; (3) the transport of any material that is infected or suspected of being infected with the plague. This order to remain in force one year from date.

The Results of Serum Treatment in Diphtheria.

Siegert[10] of Strasburg has collected the results of 37,000 cases of diphtheria in which operations were performed, with the object of showing the importance of using antitoxin early in the course of the disease and in sufficiently large doses.

His work contains many interesting and extremely valuable tables, in which are presented the results of serum treatment in 69 hospitals in most of the principal cities of Germany, Austria and Switzerland, and 1 Paris hospital. These tables show not only the reduction of fatality of diphtheria under serum treatment, but also the reduction in the fatality of operated cases and in the ratio of operated cases. He selects a period of nine years, 1890-1898, and divides it into three periods; a "fore-serum" period of four years, 1890-1893; an introduction year, 1894, and a "serum" period, 1895-1898.

His first table contains the results of 36,422 operated cases, with 18,336 deaths. Of these cases 17,673 occurred in the fore-serum period with 10,701 deaths, or 60%, while 13,534 occurred in the serum period, or 35.7%. The mortality during the introduction year was 53.7%.

In the second table the general fatality from diphtheria in the fore-serum period was 41.5%

[7] Twenty-eighth Report of Local Government Board Supplement. England. P. 202.
[8] Rev. d' Hygiene. August, 1899.
[9] Official order signed by the Queen of Holland, and by the Ministers of Justice, and of the Interior, December 28, 1900.
[10] F. Siegert: Vier Jahre vor und nach der Einführung der Serumbehandlung der Diphtherie. Berlin. 1900.

and that of the serum period was 16.5%. This table embraces the results in 23 hospitals, with a total of 41,917 cases.

Another table presents the ratio of operated cases to all cases treated in 21 hospitals, and shows very plainly that the necessity for operation is diminished under the effects of serum treatment, since the ratio of operated cases in the fore-serum period was 47.2% and that of the serum period was only 27.5%. The whole number of cases considered in this table was 40,038.

The Freeing of Places from Mosquitoes for the Prevention of Malaria.[11]

Drs. Fermi and Lumbau contribute a paper detailing the methods employed to rid the city of Sassari, in Northern Sardinia, of mosquitoes. The methods employed consisted mainly of drainage of open, stagnant bodies of water, the treatment of others with petroleum where drainage was impracticable, and the uses of gaseous disinfectants and powders as culicides.

Another article in the same journal details the substances employed for the purpose of destroying mosquitoes.[12]

(To be continued.)

Recent Literature.

Arsenical Poisoning in Beer Drinkers. By T. M. KELYNACK, M.D., and WILLIAM KIRKBY, F.L.S. London: Baillière, Tindall & Cox. 1901.

This book contains a résumé of this important subject, which has been for some time and is still exciting lively interest throughout Great Britain.

The Introductory portion treats of the beginning, extent, duration, and age and sex distribution, together with the discovery of the source of the poison.

The second or clinical portion contains a full description of the symptoms and appearances noted by the authors during a long series of observations. It is quite fully illustrated with photographs showing lesions of the skin, etc. The third part, "Chemical," contains a description of the methods employed for the detection of arsenic in the beer and sugar.

A full bibliographical table is appended to the work.

INTERNATIONAL CONGRESS OF PHYSIOLOGISTS.—The Fifth Triennial International Congress of Physiologists will be held this year at Turin from September 17th to September 23d. The University Institute of Physiology, under direction of Professor Angelo Mosso, will be placed at the disposal of the congress. In connection with the congress an exhibition of apparatus will be open from September 14th to 23d.

283 WASHINGTON STREET, BOSTON, MASS.

ARSENIC IN FOOD AND DRINK.

THE wide distribution of arsenic in nature as a constituent or impurity of several ores, its common use in the arts for different purposes, and its extremely poisonous character, all tend to make it a dangerous concomitant of the life of human beings.

The recent report ("Epidemic Arsenical Poisoning Attributed to Beer," by Dr. G. S. Buchanan, London, February 7, 1901) of the Local Government Board of England presents an account of the epidemic of arsenical poisoning which has taken place in England, chiefly since November 1, 1900. A communication in the *British Medical Journal* (Letter of Dr. E. S. Reynolds) of November 24, 1900, had called attention to certain cases which had been admitted to the Workhouse Infirmary of Manchester, and also in other institutions. The disease was characterized by paralysis, wasting of certain muscles, and loss of function in certain sensory nerves. After careful clinical study, Dr. Reynolds, who reported the cases, concluded that he was dealing with arsenical poisoning. Soon afterward Dr. Tattersall, of Salford, noticed an increase in the number of cases and deaths from peripheral neuritis occurring in his neighborhood. In 18 cities and towns visited by Dr. Buchanan, under the direction of the Local Government Board, cases of the same nature had occurred to the number of nearly 4,000. Further inquiry showed that the persons affected were generally beer drinkers, and the beer, on analysis, was found to contain arsenic. The invert sugar or glucose used in making this beer was made at one factory, that of Bostock & Co., near Liverpool.

The clinical appearances presented two types, an "alcoholic type" in which the symptoms were essentially those of peripheral neuritis, not accompanied with other manifestations enabling the disease to be differentiated from what it has been

customary to term "alcoholic peripheral neuritis;" also an "arsenical type" in which the main symptoms were diverse affections of the skin — for example, erythemata, herpes, pigmentation etc. — which are seldom known to be associated with "alcoholic peripheral neuritis," but are met with frequently in cases of sub-acute or chronic poisoning resulting from ingestion of arsenious acid. Another point frequently noted was the absence of any of the symptoms of gastric and intestinal disturbances commonly attributed to arsenical poisoning. It was found to be impossible to state exactly the number of deaths which were due to this cause, in consequence of the indefinite character of the symptoms. In Manchester alone, 36 deaths were attributed to arsenic poisoning between November 25, 1900, and January 10, 1901. Of these, 23 were women and 13 were men. The amount of beer used by the sufferers varied from a pint to two gallons per day. Many drank a gallon each, daily. Samples of glucose obtained from the factory of Bostock & Co. were found to contain from .02% to .05% of arsenious acid. The glucose was made by treating Indian corn or sago starch with sulphuric acid. The source of the arsenic appears to have been the pyrites from which the sulphuric acid was made.

According to the *Sanitary Record* of February 21st, this incident has entailed a serious loss to the brewers of Manchester and other cities, since hundreds of gallons of arsenical beer were poured into the sewers. The loss also falls heavily on Bostock & Co., since they have left on their hands sugar valued at half a million dollars, contaminated with arsenic, beside the possibility of heavy demands for damages.

Examinations of the beer which was believed to be the cause of the epidemic showed quantities of arsenious acid varying from $\frac{1}{10}$ grain to $1\frac{1}{2}$ grains per gallon.

Early in December the Manchester Brewers' Association recommended the adoption of the following precautions:

That all beer in which any sugar bought of Bostock & Co. had been used should be recalled, and destroyed if found to contain arsenic; that no beer should be sent out until it had been tested and found to be free from arsenic; that a certificate of freedom from arsenic should be given for beer which had been tested for arsenic, and that only such should be sold.

Another source of arsenic in beer is suggested by Mr. Wm. Thompson. (In a paper in the *Journal of the Society of Arts*, of February 15, 1901). The malted barley used for making the beer, after being soaked in water till it begins to sprout, is dried over fires of coke or anthracite coal, the fumes of which, passing over the grain, deposit arsenic from the fuel thus used. Out of 62 samples of malt which Mr. Thompson examined, all except 7 contained appreciable amounts of arsenic, varying from $\frac{1}{200}$ grain per pound to as much as $\frac{1}{17}$ grain. He also found arsenic in 5 samples of hops and in 7 samples of yeast. Mr. Thompson also found arsenic in 8 samples of glucose, in one sample of caramel, in one of common salt, in one sample of phosphate of soda, and in one sample of nitrate of soda.

Certain tables appended to this English report would appear to confirm the suspicion that arsenical poisoning from beer had been going on for some years past. Deaths had been certified in Manchester which might have been construed as due to arsenic, to the number of 209 in 1896, 246 in 1897, 224 in 1898, 228 in 1899, and 340 in 1900.

The question of legislation having for its object the restriction of the use of arsenic in the manufacture and sale of wall papers and of textile fabrics has been brought to the attention of the Legislature of Massachusetts several times since 1872. All of the early attempts, however, were vigorously opposed by manufacturers. The writer recalls one instance in which a noted chemist from another State, who had published in a well-known cyclopedia a statement of his belief in the serious danger from certain uses of arsenic, when called before the legislative committee at the request of certain manufacturers was for some reason induced to retract his former published statement. In 1900, however, with scarcely any opposition, a law was enacted providing that dress goods or articles of dress should not be manufactured or sold in the State if they contained over $\frac{1}{100}$ grain per square yard, the limit for other materials being $\frac{1}{10}$ grain per square yard.

While the foregoing law does not apply to articles of food or drink, the analytical work in the State laboratory, which the enactment of this law has necessitated, has also given unusual opportunity to examine certain articles of food and certain drugs which were suspected of containing arsenic. The samples of glucose which were examined contained mere traces of arsenic, the quantity not being appreciable. The samples of beer examined were also practically free from arsenic. Out of 173 samples of glycerine examined, most of which were of American manufacture, 115 contained arsenic, from a trace up to 8 parts per 100,000. Out of 26 samples of phosphate of soda examined, 13 contained arsenic and one of these contained the dangerous amount of .05%, or 50 parts per 100,000. It is evidently a matter of importance that these articles, which are used internally, should be entirely free from arsenic, and the fact that many samples obtained were found to be free from this dangerous impurity shows that all can be made in the same manner by observing proper care in manufacture.

ASSOCIATE MEMBERSHIP IN THE BOSTON MEDICAL LIBRARY.

ON page 316 of this issue will be found the Amendments to the By-laws of the Boston Medical Library, which were made at the meeting held on Tuesday of this week. As the real significance of these changes may not be apparent at first sight, we desire to call to the attention of our readers their object.

The essential feature is that which provides for the creation of a class of associate members for whom the annual assessment shall be one-half of that paid by the active members. This new class of members is open only to young men who have received their medical degree within five years, or to those who live outside the limits of Old Boston or those parts of Roxbury now included in the Suffolk District of the Massachusetts Medical Society.

The expenses of running the Library have naturally been greater in its new building. As was expected it was found to be necessary to increase the annual assessment to ten dollars. The members of the Library have cheerfully paid this increased amount and have felt that the improved facilities and attractions of the new building amply justified the increased expense. The financial support of the Library is therefore assured. It has been felt, however, that the growth of the library membership would be very much hindered by the increased assessment.

The gain in new members must come chiefly from the young men just entering practice and from those living outside the city limits. Men of these two classes would naturally hesitate to join the Library and to commit themselves to the yearly payment of ten dollars. To the younger men this would be a heavy burden, while those living out of town would feel that they would not use the Library enough to justify this outlay. By the creation of a class of associate members with a five-dollar assessment, it is believed that many will avail themselves of the advantages which the Library offers, who would otherwise feel themselves debarred.

The Library building was erected in chief part by the personal sacrifices of the physicians in and around Boston. They felt that a new building meant new members and wider spheres of influence for the Library.

MEDICAL NOTES.

PHYSICIANS IN CANADIAN PARLIAMENT.— According to the *Medical Record*, eighteen doctors have been elected members of the new Dominion Parliament. Among the few conservatives who escaped the landslide, it is a gratification to see the name of Dr. Roddick. It would have been a distinct loss to the medical profession of Canada had he been defeated, especially when the efforts to establish a licensing board for the Dominion are within a reasonable distance of success. Dr. Roddick has given much time, and has shown energy and ability in overcoming the difficulties in the way of this scheme, and has rendered a public service in the interests of not only the medical profession but the community at large, deserving the highest praise.

WILLS HOSPITAL OPHTHALMIC SOCIETY. — The members of the Staff of Wills Hospital of Philadelphia have formed themselves into an association known as the Wills Hospital Ophthalmic Society. The object of the association is to "promote the scientific usefulness of the institution by the discussion of papers and the exhibition of patients who have been under the care of the members of the attending staff." Meetings will be held twice a month, and reports of the proceedings will be published.

MARRIAGE REFORM LAW IN MINNESOTA. — The State Senate has recently reconsidered and finally passed a bill prohibiting the marriage of insane, epileptic and idiotic persons and requiring a medical certificate of all applicants for marriage licenses. Amendments to the bill as first introduced were adopted, thereby permitting the marriage of feeble-minded persons over forty-five years of age, either man or woman. The bill is reported to have passed by a vote of 34 to 17.

A SAVING OF LIVESTOCK. — It is reported from Washington, through the Department of Agriculture, that over $6,000,000 worth of young animals were saved during 1900 by the prompt application of remedial measures for blackleg. Over 2,500,000 doses of the vaccine were distributed by the Department during the year.

DEATH OF PROFESSOR MANASSEIN. — It is announced that Professor Manassein, the founder and for many years the editor of the well known Russian medical journal, *Vratch*, is dead at the age of 60.

PLAGUE IN WEST AUSTRALIA. — It is reported by the governor of West Australia that a white man and a Chinaman have died of bubonic plague. There is no reason to fear a spread of the disease.

HOSPITAL FOR TUBERCULOSIS IN WISCONSIN. — A bill is before the legislature of Wisconsin, to provide a hospital for the care of incipient cases of tuberculosis.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 27, 1901, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: diphtheria 89, scarlatina 39, measles 95, typhoid fever 5.

SCARLET FEVER AT KEENE, N. H. — The scarlet fever situation in Keene and vicinity is said to be improving. There have been several new cases, but the number of deaths is growing smaller. Five deaths occurred in Keene and in Swanzey last week, and new cases were reported, but no deaths have occurred for two days. Eleven of the new cases are in families hitherto free from the disease.

PRECAUTIONS AGAINST SMALLPOX. — Owing to the appearance of a case of smallpox in Digby, Nova Scotia, the Boston Board of Health has had the crew of the steamer *Boston*, running from Yarmouth to this port, vaccinated. The crew of the Dominion Atlantic Line steamer, *Prince George*, were vaccinated at Yarmouth. No apprehension is felt of the introduction of the disease from this source.

AWARD OF BOYLSTON PRIZE FOR 1901. — It is officially announced that the Boylston prize for this year has been awarded to Howard Crawley, S.B., of Cambridge, for an essay on "Histological Changes Occurring in the Intestinal Cells of the Newt during the Absorption of Fat."

NEW YORK.

A NEW LYING-IN HOSPITAL.—The Attorney General of the State has approved the certificate of incorporation of a new lying-in institution, to be known as the Manhattan Maternity Hospital and Dispensary, particularly designed for severe and complicated cases, with facilities for carrying on a large tenement house midwifery service. An amount of money has been contributed by an anonymous benefactor sufficient for the purchase of a suitable plot of land, the erection and equipment of the hospital building, and a partial endowment for a term of years. It is understood that Dr. J. Clifton Edgar, professor of obstetrics in the medical department of Cornell University, has been mainly instrumental in organizing the Maternity, and that it is to be located in the upper east side of Manhattan.

DYNAMITE EXPLOSION IN RAPID TRANSIT TUNNEL — A very severe dynamite explosion occurred on March 21st at 181st Street and Broadway, in the Rapid Transit tunnel now being constructed, which injured four workmen, and might have destroyed the lives of forty but for the prompt action of Engineer John Mullen, who with great presence of mind immediately started the air compressors, which drove out the suffocating dynamite fumes and supplied fresh air until the men could be rescued. For over half an hour they were lying face downward in the tunnel, breathing the fresh air thus furnished them. The shaft at this point is 131 feet deep.

QUALIFICATIONS OF PRESIDENT OF STATE COMMISSION IN LUNACY. — Governor Odell has signed the bill, recently passed by the Legislature, providing that the president of the State Commission in Lunacy shall be a physician of ten years' experience, who has had five years' experience in the treatment of mental and nervous diseases, or two years' experience in the treatment of committed insane.

TWO CENTENARIANS.—Martin Dyer died in New York on March 3d, at the age of one hundred and one years. He was born in Ireland, November 24, 1800, and came to America in 1835. His descendants number 40 grandchildren and 110 great-grandchildren. Mrs. Harriet Matteson has recently died at Dunkirk, N. Y., at the reputed age of one hundred and four.

RESIGNATION OF FRANCIS DELAFIELD, M.D. — Dr. Francis Delafield, who has been the honored incumbent for many years, has resigned the chair of practice of medicine in the College of Physicians and Surgeons, and Dr. Walter B. James, one of the instructors in general diagnosis, has been appointed to the position.

MIDDLETON GOLDSMITH LECTURE. — The Middleton Goldsmith Lecture, for 1901, the full text of which is given in this issue, was delivered March 26th by Prof. Charles S. Minot, of the Harvard Medical School, on the subject, "The Embryological Basis of Pathology."

AMENDMENTS TO BY-LAWS OF BOSTON MEDICAL LIBRARY.

The following amendments to the By-Laws of the Boston Medical Library were made at a special meeting Tuesday, March 26, 1901:

Wherever the word "Association" occurs in the By-Laws it shall be omitted and the word "Library" inserted.

Amend Article XIII. so that it shall read as follows: —

The Membership of the Library shall consist of Active Members, Associate Members, and Life Members.

Any member of the Massachusetts Medical Society, Massachusetts Dental Society, Massachusetts College of Pharmacy, and such other person as may, on application, be approved by the Executive Committee, may become an active member by enrolling his name in the list of active members at the Library and paying the assessment for the current year.

Any person eligible to active membership, provided that not more than five years have elapsed since he received his medical degree, may become an associate member for all or any part of the said term of five years by enrolling his name in the list of associate members at the Library and paying one-half the assessment for active members yearly.

Any person eligible to active membership, provided he live outside the limits of Old Boston or that part of Roxbury now included in the Suffolk District of the Massachusetts Medical Society, may become an associate member by enrolling his name in the list of associate members at the Library and paying one-half the assessment for active members for the current year.

Associate members shall have all the privileges of active membership except the right to vote or to borrow books from the Library.

Any active or associate member, or any person eligible to active membership may, by the payment of $150 at any one time, become a life member, and be thenceforth exempt from payment of the annual assessment. Life members shall have all the privileges enjoyed by active members except that they shall not be allowed to vote on the question of the amount of the annual assessment.

All money which shall be received for life memberships shall be invested by the Treasurer, and only the income thereof shall be employed for the uses of the Library.

Amend Article XIV. so that it shall read: —

The annual assessment for active members shall be such as is directed by vote of the active members at the annual meeting, and shall be payable in advance.

THE RIGHT TO WILL ONE'S BODY FOR SCIENTIFIC INVESTIGATION.

THE *New York Medical Journal* comments as follows on a recent ruling of the Supreme Court of California: "The Supreme Court of California, in the case of Enos *versus* Snyder, has laid down a ruling, the results of which appear to us to be very regrettable from a scientific point of view. It has decided, in a contest between next of kin, on the one hand, and claimants under a will, on the other hand, for the possession of a corpse, that a man cannot by will dispose of that which, after his death, will be his corpse. The custody of the corpse and the right of burial belong to the next of kin in preference to the administrator. This view is based on the fact that the general English and American legal authorities establish the rule that, in the absence of statutory provisions, there is no property in a dead body. If this ruling is correct, the sooner statutory provisions are obtained enabling a man who feels that a great benefit to humanity will accrue, through increase of medical knowledge, by the continuance post mortem of an investigation into his case, or that new light may be shed upon anthropological, psychological, or other scientific problems, to authorize by will such use of his corpse, the better. We commend this subject to the consideration of the Medico-Legal Society."

Correspondence.

NOTES ON X-LIGHT: THE CONTROL GUINEA PIGS.

MR. EDITOR: — In this journal for February 14th I showed that x-light could kill. That an invisible radiation of which none of our senses make us conscious should be able to produce death, leaving no sign to the eye, is one of the most remarkable facts in the domain of medicine, and full of promise for therapeutics. These experiments were published chiefly because: (1) in them for the first time the participation of electricity in the results was certainly excluded; (2) they were the first that proved that x-light could act below the surface of the body; (3) they showed that x-light had the power to profoundly affect the life processes. As the experiments have been doubted, the deaths being attributed to other causes, I report the condition of the control guinea pigs. These were kept in the same pen with those exposed to x-light. All were given the same food and care. I took entire charge of the animals during the whole of all the investigations, that nothing might escape my observation. Some of the control guinea pigs gave birth to young that have now reached the adult stage. No death or visible sickness has occurred except in those exposed to x-light. If activity, appetite, fine coats and bright eyes are signs of health, these control animals are well. My chief object in these investigations was this: A friend had been operated on for cancer, which I expected would return. As no second operation would have been practical, I desired to know whether x-light could be used to affect cell growth in the interior of the body; and if it could, whether the results could be accomplished without danger of burning. The experiments cause me to believe that internal cancers beyond the reach of the knife will be favorably affected by x-light. There is no more important investigation in the realm of medicine than the study of the effects of x-light on internal cancer.

Very truly yours,

WILLIAM ROLLINS.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 16, 1901.

Deaths reported 3,062; under five years of age 889; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whoop-

ing cough, erysipelas, fevers and consumption) 667, acute lung diseases 603, smallpox 6, measles 12, diphtheria and croup 94, cerebro-spinal meningitis 20, diarrheal diseases 49, whooping cough 20, erysipelas 19, consumption 367, scarlet fever 47, typhoid fever 27.

From whooping cough, New York, 5, Baltimore, 3, Pittsburg, 3, Philadelphia, 2, Providence, Boston, Worcester, Chelsea, Malden, Chicopee and Springfield, 1 each. From cerebro-spinal meningitis, New York, 5, Baltimore, 3, Boston, 2, Somerville, 2, Pittsburg, Providence, Lowell, Gloucester, Everett, North Adams, Clinton, and Fitchburg, 1 each. measles, New York, 6, Pittsburg, 3, Boston, 2, Lawrence, 1. From scarlet fever, New York, 29, Philadelphia, 9, Pittsburg, 3, Boston, 5, Brockton, 1. From typhoid fever, New York, 10, Pittsburg, 9, Philadelphia, 3, Providence, 1, Lowell, 2, Fall River and Newburyport, 1 each. From smallpox, 6 cases in New York City.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending March 2d, the death rate was 215. Deaths reported, 4,858; acute diseases of the respiratory organs, (London) 501, whooping cough 129, diphtheria 62, measles 109, fever 25, diarrhea 47, scarlet fever 23.

The death rates ranged from 14.1 in Oldham to 38.2, in Plymouth, Birkenhead, 22.7, Birmingham, 21.4, Blackburn, 21.7, Bolton, 19.1, Bradford, 19.1, Brighton, 19.2, Bristol, 24.7, Cardiff, 19.8, Croyden, 15.5, Derby, 18.1, Halifax, 25.4, Hull, 22.3, Leeds, 22.2, Leicester, 13.9, Liverpool, 3.10, London, 20.9, Manchester, 22.8, Norwich, 17.0, Nottingham, 22.0, Portsmouth, 21.2, Preston, 16.1, Salford. 22.6, Swansea, 24.3, West Ham, 16.9, Wolverhampton, 26.0.

METEOROLOGICAL RECORD.

For the week ending March 16th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

SOCIETY NOTICES.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY. — The Surgical Section will meet at the Medical Library, Number 8, The Fenway, on Wednesday evening, April 3, 1901, at 8.15 o'clock.

Papers: "A Case of Fracture of Cervical Vertebræ. Operation. Recovery."

"A Case of Hemorrhage from the Middle Meningeal Artery. Operation. Recovery." Both cases reported by Dr. S. J. Mixter.

"Two Cases of Operation for Ruptured Aneurism of the Abdominal Aorta." By Dr. J. C. Munro.

"A Case of Intussusception in a Girl of Sixteen." By Dr. F. G. Balch.

F. G. BALCH, M.D., Secretary,
279 Clarendon Street.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the society will be held in Sprague Hall, Medical Library Building, Fenway, on Monday, April 1st, at 8.15 P.M. Subject, "Inebriety."

Paper, by Dr. V. A. Ellsworth: "Treatment of Delirium Tremens."

To take part in the discussion: Dr. J. Frank Perry, Dr. Charles E. Woodbury, Dr. Owen Copp, Dr. H. G. Beyer, Dr. George A. Sargent, Dr. F. M. Johnson, Dr. Charles F. Folsom and others.

ARTHUR K. STONE, M.D., Secretary,
657 Boylston Street.

AMERICAN SURGICAL ASSOCIATION. — The American Surgical Association will hold its annual meeting at Baltimore, Maryland, May 7, 8, 9, 1901.

AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS. — The American Association of Pathologists and Bacteriologists will hold its first Annual Meeting in Boston, April 5, 6, 1901.

AMERICAN LARYNGOLOGICAL ASSOCIATION. — The Twenty-third annual meeting of the Association will be held at New Haven, Conn., Monday, Tuesday and Wednesday, May 27, 28, 29, 1901, under the presidency of Dr. Henry L. Swain, of New Haven.

RECENT DEATHS.

DR. JOHN SARGENT, the oldest physician in Jefferson County, died March 19th, at his home in Woodville, N. Y., at the age of eighty-seven.

DR. G. W. C. WREN, aged twenty-seven years, of the house-staff of St. Vincent's Hospital, New York, died in the hospital on March 23d, of typhoid fever.

DR. HUGO A. LEVISON, a promising young New York physician, died on March 17. He was graduated from the College of Physicians and Surgeons, New York, and afterwards pursued a course of post-graduate study in Europe. At the time of his death he was connected with the Vanderbilt Clinic, the West Side German Dispensary, and the outdoor department of Roosevelt Hospital.

BOOKS AND PAMPHLETS RECEIVED.

Tuberculosis in Pennsylvania. Guy Hinsdale, A.M., M.D., Philadelphia.

Surgical Operations in Hospitals for the Insane. By William Mabon, M.D. Reprint. 1900.

Contribution to the Therapy of Encephalocele. By Carl Beck, M.D., New York. Reprint. 1900.

Transactions of the American Climatological Association for the Year 1900. Vol. XVI. Philadelphia. 1900.

Two Hundred and Thirty-seven Consecutive Abdominal Sections. By Charles Gilbert Davis, M.D., Chicago. Reprint.

The Circulation in the Nervous System. By Herman Gasser, M.D., Platteville, Wisconsin. Journal Publishing Co. 1901.

Tuberculosis, and How to Combat It. Prize Essay. By S. A. Knopf, M.D., New York. New York: M. Friestack. 1901.

Case of Gastric Carcinoma, Treated Successfully with Platinic Chloride. By John Murray, M.D., Carbon Hill, Ill. Reprint.

Hypnotism and Suggestion. In Therapeutics, Education and Reform. By R. Osgood Mason, A.M., M.D. New York: Henry Holt & Co. 1901.

Chloroform. A Manual for Students and Practitioners. By Edward Laurie, M. B., Edin., M.R.C.S., Eng. London: J. & A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1901.

Diet and Food, Considered in Relation to Strength and Power of Endurance, Training and Athletics. By Alexander Haig, M.A., M.D., Oxon., F.R.C.P. Third edition, illustrated. Philadelphia: P. Blakiston's Son & Co. 1901.

Hypnotism. A Complete System of Method, Application and Use, Prepared for the Self-Instruction of the Medical Profession. By L. W. DeLawrence, Instructor at the School of Hypnotism, etc., Pittsburg. Illustrated. The Henneberry Co. 1901.

A Manual of Practical Hygiene for Students, Physicians and Medical Officers. By Charles Harrington, M.D., Assistant Professor of Hygiene in Medical School of Harvard University. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1901.

Aix-la-Chappelle (aachen) as a Health Resort. By Drs. Alexander, Beissel, Brandis, Goldstein, Mayer, Rademaker, Schumacher and Thissen, of Aix-la-Chappelle. English edition translated with the sanction of the Civic Authorities. By James Donelan, M.B., M.C.H., B.A.O. Second print. London: J. & A. Churchill. 1899.

Original Articles.

DISEASES OF THE MYOCARDIUM.[1]

BY HENRY JACKSON, M.D., BOSTON,

Assistant Visiting Physician, Boston City Hospital.

Diseases of the heart may be broadly classified as dependent upon pathological changes in the valves of the heart, or in the muscular substance of the heart, and I wish this evening to draw your attention to the latter class of cases. We find by post-mortem examination that a pretty large number of cases, in which, during life, there have been various signs of improper or insufficient action of the heart, show no evidence of valvular lesion to account for the disturbance in the functions of the heart. Many so-called "cardiac cases," presenting during life all the signs of heart disease, show no valvular lesion, and the primary cause of the disturbance may lie far removed from the heart.

Further, in all forms of acute infectious disease, though more markedly in some, as diphtheria and typhoid fever, than in others, degeneration of the heart muscle may lead to weakness of the action of the heart, a symptom which in the individual case may far outweigh in importance any symptoms directly dependent upon the specific disease which has caused the heart failure. But this evening we wish to speak of chronic forms of disease of the myocardium which give rise to a train of symptoms properly spoken of as heart disease.

We recognize still more the value of an accurate diagnosis as to the condition of the muscular portion of the heart, when we consider that in the majority of cases valvular disease of the heart becomes of importance to the individual affected only when and in so far as the myocardium is affected, and the conservative hypertrophy, compensation, gives way to the condition known as non-compensation. Exceptions to this general rule occur, of course, in acute malignant valvular disease, and in disease of the valves which causes a roughening of the surface, which may form the nidus for the formation of emboli of dangerous import to the patient. Valvular disease in itself may exist for years without giving rise to symptoms which endanger the health or life of the patient; whereas dilatation of the heart, accompanied by irregular or intermittent action, indicates that the health of the patient is seriously impaired, whether the disturbance is dependent upon some long-standing valvular lesion or upon some pathological process outside of the heart. In the latter instance the patient has already reached the danger line, and in order to enable the patient to carry on his usual work we must, by appropriate treatment, strengthen the heart so that the weakened muscle may be able to carry on its work.

Disease of the myocardium does not receive in our textbooks the important consideration which it deserves, this branch of heart disease being summarily despatched, while many chapters are written on the accurate differential diagnosis of the various valvular lesions, and this, too, when we know that the diagnosis is not seldom proved to be wrong by the pathologist.

Even in the consideration of a case of valvular disease the important points in the treatment and management of the individual case are not, What is the lesion? but, what effect has that lesion produced upon the heart itself, namely, the size of the heart? Is hypertrophy or dilatation the leading factor in causing enlargement of the heart? Is the action regular, and what is the character of the pulse wave?

The discovery of the probable existence of an organic valvular lesion must, of course, indicate to us that rigid rules are to be defined as to the course of life to be followed by our patient; but this fact in itself by no means proves that the patient must consider himself as an invalid or even withdraw from his usual active and, perhaps, arduous labors. Further, we must bear in mind that the existence of a murmur does not necessarily imply the presence of an organic valvular lesion. In the first place we have the many instances of the so-called "hemic" or functional murmurs. These cases form a large class in the individuals who consult us for heart trouble, in that, in anemic persons especially, we see so prominently dyspnea, palpitation, cardiac pain and rapidity of action — all symptoms associated in the mind of the laity with heart disease, and too often in the mind of physicians. In such cases, careful diagnosis as to the size of the heart, and proof that the heart is capable of doing a proper or sufficient amount of work, show us that the alarming symptoms are dependent upon some functional disturbance of the heart, and not upon organic disease of the valves or myocardium.

In the second place, murmurs are frequently heard in disease of the myocardium where no valvular lesions are found post mortem; this applies, in my experience, to murmurs heard in the mitral and tricuspid areas. The murmurs heard in such cases are not comparable to hemic murmurs, in that they indicate a real regurgitation dependent upon non-closure of the valves, but the failure of the valves to close is dependent upon a relative insufficiency of the valves; with the dilatation of the ventricle, the ring of the valvular orifice is enlarged, and the valve curtains that formerly sufficed to close the opening are no longer capable of meeting across the enlarged area, and so a leak occurs.

Therefore, in the consideration of a case of heart disease, two prominent facts should always be before us: (1) That heart disease does not mean valvular disease, and (2) that murmurs evidently pathognomonic of regurgitation do not prove the existence of organic disease of the valve curtains.

Pathologically, diseases of the myocardium may be classified under the following heads: (1) Disturbance of the circulation; (2) inflammatory processes; (3) degeneration; (4) various new

[1] Read before the Boston Society for Medical Improvement, February 4, 1901.

formations — tumors; (5) hypertrophy and dilatation.

I intend this evening to speak only of the changes which give rise to symptoms which produce the clinical picture of "heart disease."

(1) *Disturbances of the circulation.* — Local anemia, dependent upon stoppage of one of the branches of the coronary arteries, is always of serious import in that these are terminal arteries. The usual pathological cause is sclerosis, calcification and thrombosis, this being the natural sequence of events. If the disturbance takes place near the beginning of the artery, large areas may be affected and sudden death may occur. Where sudden death occurs without other demonstrable cause, it is always important to examine with care the coronary arteries in search of embolism or thrombosis. If the closure be more gradual, and the artery affected of smaller size, we have as the result a gradual degeneration of the muscles supplied by that artery, and the formation of a fibrous tissue which in time causes a weakness of the heart wall, and may lead to the so-called aneurism of the heart substance. If the closure be sudden of the smaller branches, we may have acute softening of the heart muscle and rupture. I have seen, in consultation, a lady who was suddenly awakened at night by a sharp pain in the cardiac area. When I saw her the next day there was much pain, a weak, irregular heart action, with feeble pulse; only a portion of the cardiac beats produced a pulsation at the wrist. Three days later she died suddenly, and the pericardium was found filled with blood; the heart was ruptured in two places, and there was found a complete stoppage of the left coronary artery.

Again we may have, as the result of embolism or thrombosis of the smaller branches of the coronary arteries, the formation of a hemorrhagic infraction, which in turn may be absorbed and give rise to a chronic localized myocarditis, with the formation of cicatricial tissue in place of the destroyed muscular tissue, this being one of the causes of aneurism of the heart. Such cases have been admitted to my wards with all the signs and symptoms of chronic heart disease.

(2) *Inflammatory processes.* — In acute parenchymatous disease we find the pathological cause of the disturbance associated with many acute infectious diseases. Purulent myocarditis may be dependent upon the ordinary pus-producing bacteria, as seen in sepsis, or may be due to the gonococcus, as in a unique case reported by Dr. Councilman, in which sudden death occurred from rupture of the heart. Chronic fibrous myocarditis may lead to a gradual weakening of the heart by the replacing of the muscular substance by the newly formed fibrous tissue; the essential cause of such a process usually lies in sclerosis of the coronary arteries, as already described.

(3) *Degeneration.* — Under the head of what Orth calls "regressive disturbance of nutrition," we place simple atrophy and brown atrophy, pathological processes which possess but little clinical interest. Of great importance is fatty degeneration, a condition usually found to a greater or less degree on microscopic examination of all cases of dilatation of the heart.

(4) *Tumors.* — Tumors may be varied, but are rare, and when present do not usually give a picture of chronic heart disease, with the single exception of gummata; cases of syphilis of the heart have come under my notice in individual practice or consultation, which presented the usual symptoms of heart disease.

(5) *Hypertrophy and dilatation.* — The conditions just mentioned are those which may, and occasionally do, give rise to symptoms classified as "cardiac," presenting a picture of heart disease, broadly speaking; but under the pathological classification of hypertrophy and dilatation we find the vast number of cases which during life have presented all the classical features of heart disease — dyspnea, edema, weak and rapid pulse with gradual failure — in which the question arises whether our patient be suffering from valvular disease, or some disease of the myocardium, a condition for which I prefer the name "parietal disease of the heart," as not limiting us in diagnosis to any one pathological condition, as the cause of the disturbance may be varied.

Hypertrophy is dependent upon increase in size of each individual muscular fibre, and dilatation is due to enlargement of the cavities. With the increase in size of the muscular fibres, we have, as I have stated, in most cases more or less fatty degeneration of the individual fibres. Pathologically and clinically the two conditions go hand in hand, a certain degree of dilatation being usually associated with hypertrophy. Clinically it is of much importance to bear in mind that, when by percussion we find that the heart area is enlarged, we have already a certain degree of dilatation of the cavities. Hypertrophy is conservative, the index of nature's effort to overcome the obstruction which interferes with the proper action of the heart; whereas dilatation is evidence that the time is coming when the heart muscle will fail to respond to the call for extra work made upon it. So long as hypertrophy predominates over dilatation, we have "compensation."

The normal adult heart may be considered as weighing from 270–310 grammes, the size varying within certain limits with the age and size of the individual.

I wish to draw your attention to some of the most important factors causative of hypertrophy and dilatation, always bearing in mind that this condition is not a disease in itself, but is the result of various pathological conditions, often far removed from the heart itself.

Clinically, we recognize hypertrophy by the strength of the pulse, the heaving of the apex beat, and the force of the heart sounds; note, I do not say by the size of the cardiac dullness, as this bears no relation at all to the thickness of the muscular walls of the heart. Percussion of the heart area gives no data to determine the amount of hypertrophy, for if the ventricle be increased in thickness half a centimetre, we have a great increase

in the muscular substance; whereas an increase in the area of cardiac dullness of this extent would be scarcely perceptible. As soon as the area of cardiac dullness is perceptibly increased to the right or left, we have already an increase in the size of the ventricle. The recognition of hypertrophy is not of such importance to the individual as dilatation, as his safety lies in hypertrophy, whereas in dilatation we have a sign which may threaten his life.

By percussion we determine the size of the heart, while by auscultation and by the character of the pulse we determine whether the hypertrophy or the dilatation be the predominate factor. By auscultation we find in dilatation that the normal booming character of the heart sounds is lost; the sounds are often described as "valvular," whatever that may mean. A marked sign of cardiac weakness is found in reduplication of the sounds, a condition well described as the gallop rhythm, as this term expresses exactly what we hear; the normal sound of lub-dub is replaced by the abnormal sound lub-a-dub. We often find that after the proper use of digitalis, the gallop rhythm entirely disappears, to appear again only when the heart muscle no longer responds properly to the work it is called upon to perform. The pulse is weak, rapid, irregular or intermittent; irregularity of rate and rhythm is of far greater importance as an index of weakness of the heart than occasional intermittency.

The most important condition indicative of cardiac weakness is met with when there is a marked discrepancy between the number of beats of the heart and the pulsation transmitted to the radial artery. Though this may be spoken of as the acme of cardiac weakness, it is a sign which has apparently received but little attention from writers on diseases of the heart. It may be seen not only in marked dilatation of the cavities of the heart, but also in advanced degeneration of the heart muscle, the result of acute infectious diseases. I have seen this phenomenon in typhoid fever, in diphtheria, and in many cases of advanced heart disease with great dilatation of the cavities. I have, within a few weeks, seen a lady with excessive dilatation: the pulse was 80–90 per minute, the apex beat 130–140 per minute.

The causes of enlargement of the heart may lie within the heart itself, or outside of the heart. Taking up the first factors we have: (1) Valvular disease; (2) diseases of heart wall, including chronic myocarditis; (3) new growth in the heart.

In this paper I do not intend to speak of the effects of valvular disease upon the heart.

Howard, in his article upon hypertrophy of the heart, found in 100 cases at autopsy that valvular disease was the etiological factor in only 13, or 12% of the total number. Some years ago I examined the autopsy records of the Boston City Hospital; taking 100 consecutive cases where there was disease of the heart, I found that in 75 cases where the weight of the heart was given, that valvular disease was the cause of the enlargement in 22 or nearly 30%, a much larger proportion than Howard found, yet leaving many cases where the disturbance lay without the heart.

The causes outside of the heart may be: (1) Pericardial adhesions; (2) disease of the kidneys; (3) chronic pulmonary disease; (4) actions of drugs and poisons, especially alcohol; (5) overwork, the so-called "soldier's heart;" (6) a few cases in which the etiology is obscure; (7) last, and by far most important, arteriosclerosis, arterio capillary fibrosis.

(1) *Pericardial adhesions.*—In chronic fibrous pericarditis with adhesions, we have a most potent factor in causing enlargement of the heart. In my list of 100 cases from the City Hospital were 5 cases dependent upon adherent pericardium, and in all the heart was enormous, the weight being respectively 930, 900, 1,300, 1,090 and 800 grammes; in 3 cases there was in addition some valvular disease. In all of the cases there were marked symptoms of cardiac failure; great dyspnea, cyanosis, edema; in each instance the heart was found to be much enlarged and its action was weak and irregular. Howard reports 8 cases in 105 of enlargement due to adherent pericardium.

(2) *Diseases of kidney.*—In my series of 100 cases I have 5 cases of enlargement of the heart dependent upon renal disease, in which there was no general arteriosclerosis, and no disease of the coronary arteries to cause the enlargement. These cases are of far less importance than the large number of cases in which there is general arteriosclerosis with more or less secondary disease of the kidneys.

(3) *Chronic pulmonary disease.*—The enlargement due to chronic pulmonary disease is limited to the right heart, and the symptoms are usually marked by those dependent upon the primary disease. I have seen in private practice such a case in which the dilatation of the heart caused the most prominent symptoms. A man of sixty came to my office suffering from extreme dyspnea; he was cyanotic; there was marked pulsation of the vessels of the neck, enlargement of the right side of the heart and a loud murmur in the tricuspid area. There was consolidation of half the right lung. Under the exhibition of digitalis the venous pulse and tricuspid murmur disappeared, and the man returned to work for two years.

(4) *Systemic poisons.*—Alcohol, and perhaps the excessive use of tobacco, though the latter is much more apt to give rise to functional disturbances. Alcohol used to excess plays an important rôle in the etiology of enlargement of the heart. In excessive drinkers it is not rare to find symptoms pointing to great enlargement of the heart with entire loss of compensatory hypertrophy. Dyspnea is often extreme with cyanosis and general anasarca, independent of lesions in any organs other than the heart.

Aufrecht has called attention to this disease, giving the name "alcoholic myocarditis." He considers the first lesion to be a dilatation of the cavities of the heart, the first pathological lesion

being interstitial inflammation with fragmentation of the muscular fibres. In my review of the hospital cases, I found 3 well marked cases. In all these was marked enlargement of the heart; in none of the cases was there any anatomical lesion found sufficient to account for the increase in size, no arterial, renal or valvular disease.

CASE I. A man, age twenty-nine. Great alcoholic excess. For several weeks dyspnea and cough. Examination showed a pale, fat, cyanotic man. The heart was much enlarged to the right and left; it was irregular and intermittent; no murmurs. The heart weighed 575 grammes. Dr. Councilman added the following note to the autopsy: "This case is obscure. Death has apparently been the result of a loading of a weak heart." There was no anatomical lesion so far as could be ascertained, of heart hypertrophy. It is possible it was hypertrophy from alcohol, similar to the "Munich heart." In the other similar cases the hearts weighed, respectively 450 and 590 grammes.

Clinically it is not unusual in hard drinkers to find a moderate grade of cyanosis, some dyspnea and enlargement of the cardiac area, with a corresponding weakness of the action of the heart. It is probable that the majority of such cases are the result of such a pathological lesion as I have described, a dilatation of the cavities of the heart, rather than upon fatty degeneration of the muscle. The diagnosis of "fatty heart" is common, but pathological records do not confirm the supposed frequency of this lesion.

Fraentzel is inclined to entirely deny that fatty overgrowth of the heart, the so-called infiltration, has any importance in the etiology of cardiac disease. A marked overgrowth of fat is frequently found at autopsy in individuals who have given no signs of insufficiency of the heart during life.

(5) *Hypertrophied heart from overwork.* — Under this head we class cases which present symptoms of disturbance in the action of the heart, apparently the result of excessive bodily work. The matter was first brought to the attention of the profession after the Rebellion, the name "soldier's heart" being given by Weir Mitchell and Da Costa. Similar cases were seen in Germany after the Franco-Prussian War. Howard gives 5 cases of this category in his list of 105 cases of hypertrophy of the heart.

I have had under my care at the hospital a man of forty-five years, who had done especially laborious work; no history of alcohol; no renal or pulmonary disease. He had great dilatation, rapid, irregular heart, and finally death from pulmonary infections. No arteriosclerosis.

(6) *Cases obscure in etiology.* — As in these cases of "overwork," so there are others in which enlargement of the heart is found without well marked pathological cause. Hydremic, general plethora and disturbance of the nerves which regulate the action of the heart may be called up to explain the condition, all of the cause being, perhaps, rather suggestive than capable of demonstration. The enlarged heart of the Munich beer drinkers may, perhaps, be more properly classified under "Plethora" than under the cases of direct alcoholic poisoning, as the disease seems to be dependent rather upon the excessive amount of fluid ingested than upon the small amount of alcohol which that fluid contains.

The enlargement in Graves' disease in exophthalmic goitre, may properly be cited as an instance of the result of an interference with the cardionervous supply. For several years I have had under observation a case of this disease with a considerable enlargement of the heart and the attendant symptoms of weakness of the heart.

A very interesting example of cases of this indefinite etiology has come under my personal observation. A lady, of fifty odd years, had been for many years short of breath on exertion. During the last year of her life she suffered severely, and for many months before her death was unable to lie down at night, and slept in an armchair. She was stout, of florid complexion; the smaller veins were prominent. On the slightest exertion her respiration was labored. She was of the so-called "apoplectic type." The heart was much enlarged and its action weak and irregular; for many months before her death there was great edema of the legs, so that serum constantly oozed from the broken skin. A more marked picture of the extreme sufferings of "heart disease" it is difficult to imagine. The autopsy was made by Dr. Councilman, and I give you the notes which bear upon the subject in hand: "Body small." Edema of lower extremities. Subcutaneous fat abundant. Liver large with corset furrow well marked. In each pleural cavity a small amount of slightly blood-stained fluid. Lungs somewhat emphysematous, and a slight bronchitis in lower lobes. Both layers of pericardium smooth. Heart enormously enlarged; the cavities distended with fluid blood; weight 720 grammes (normal 280 for women of this size). The entire heart hypertrophied and dilated, especially the left side. Aortic valve competent; the orifices of the heart share in the dilitation; coronary arteries normal, splenic, mesenteric and renal arteries normal.

Microscopic examination. — Diffuse fatty degeneration of the heart. Diffuse increase in the connective tissue and a slight fatty degeneration of the kidney.

Dr. Councilman adds: "I am somewhat at a loss to explain the excessive hypertrophy of the heart. There is not any valvular lesion sufficient to cause it: there is no arteriosclerosis. There is no more disease of the kidney than we would expect in a person of that age. It is possible that the hypertrophy might be due to excessive action of the heart brought about by nervous excitability, or possibly to a condition of plethora. It is one of those rare cases of heart hypertrophy for which no sufficient mechanical cause can be found."

(7) *Arteriosclerosis.* — We come now to the last, and by far the most important, cause of enlargement of the heart, to a cause explanatory of a large proportion of cases classified clinically as "cardiac," "weak heart," "cardiorenal," or "fatty heart," namely arteriosclerosis.

In my list of 100 autopsies I find a record of 32 cases of disease of the heart dependent upon arteriosclerosis, and in only 4 was the weight of the heart under 400 grammes. Arterio capillary fibrosis, a thickening of the intima and middle coat of the smaller arteries, whereby their lumen is diminished in size and the work of the heart much increased. Physiologically, in old age there is a certain grade of this process which in youth is pathological. It is when the disease appears in youth that it becomes of importance and gives rise to the axiom, "That a man is as old as his arteries."

As to the etiology of the disease, in one-third of the cases there is a history of great alcoholic excess, but in 11 of the 32 cases the statement is made that no apparent cause for the disease was found. It is noteworthy that articular rheumatism had preceded the onset of symptoms in only 2 cases; in neither was there valvular disease, as no valvular cases are reported in the class of heart disease dependent upon arteriosclerosis.

As to age, these cases do not correspond with Howard's, who reports that the greater proportion of his cases of arteriosclerosis were in the prime of life, where the age is given in my cases the following data may be cited: Twenty to thirty, 3 cases; thirty to forty, 4 cases; forty to fifty, 3 cases; fifty to sixty, 9 cases; sixty to seventy, 6 cases. In all of the younger cases alcoholic excess was a marked feature in the probable etiological factors. In 4 of the cases dilatation is not mentioned: in the others there was general hypertrophy and dilatation of both sides of the heart.

In 5 cases there was such a marked dilatation of the cavities that there was a relative insufficiency of the valves demonstrable at post-mortem examination. In all of these cases there were loud murmurs heard during life.

The following is a brief history of one of these cases:

Man, age forty-nine. Hard drinker. For many months he had suffered from dyspnea; marked edema of the extremities; heart enlarged 1½ inches to the left of the nipple line, and 1 inch to the right of the sternum. Systolic murmur at the apex. Pulse irregular and intermittent. Nine months later he again entered the hospital, when his symptoms had increased to severe orthopnea with deep cyanosis. There was a loud systolic murmur at the apex transmitted to the axilla and a double murmur at the base in the aortic area. The action of the heart was very irregular and intermittent. In the urine was a trace of albumin with a few casts. He suffered from dyspnea for three months and died.

Autopsy. — Heart, 820 grammes. General hypertrophy and dilatation; relative insufficiency of the mitral and aortic valves; chronic passive congestion of the kidneys.

This case may be well cited a typical, though extreme case of arteriosclerosis. The man was a hard drinker, no history of rheumatism, dyspnea, increasing to orthopnea, cyanosis, great enlargement of the heart and death. It is a good example of the cases in which murmurs are heard, and yet there is no valvular lesion.

Several of the cases recorded died of cerebral hemorrhage or entered unconscious: all who were in a condition to give an intelligent account of their symptoms gave a history of shortness of breath or dyspnea, extending over a considerable period; in several instances for years. Several of the cases were cyanotic, and orthopnea was noted so severe that the patients were unable to lie down in bed. In half the cases there was marked edema, and in several general anasarca. Associated with the dyspnea were the usual symptoms of cough, expectoration — at times bloody — and the presence of râles in the chest indicative of bronchitis.

Examination of the heart. — It was enlarged in 16 cases according to clinical observation. In 6 cases the heart area is described as normal. In many of the cases the action was weak and the heart markedly irregular and intermittent. The pulse was usually weak, rapid, intermittent and irregular, though in 8 cases it is mentioned as regular and of good strength. Murmurs were detected in 10 of the cases. In 7 of these cases the murmur was situated at the apex and was transmitted into the axilla, as is the case in the murmur of mitral regurgitation. In none of these cases was there found, post mortem, a pathological condition explanatory of the cause of the murmur. In one case there was a systolic murmur in the aortic area where post-mortem there was found a slight sclerosis of the aortic valve which probably gave rise to a certain degree of constriction. In 2 cases a double murmur was heard at the aortic area and post-mortem the aortic valve was demonstrated to be relatively insufficient, as a result of the dilatation of the left side of the heart. As murmurs indicative of imperfect closure of the valves were heard in one-third of the cases of arteriosclerosis, it is evident that the presence of such murmurs cannot be offered as evidence of structural lesions of the valves.

In 16 of the cases a trace of albumin with casts was found in the urine. In 14 of the cases there was structural disease of the kidney, consisting of chronic diffuse nephritis of moderate grade in the majority of the cases, while in 3 instances a small granular kidney was found post mortem. The immediate cause of death was cutaneous hemorrhage in 4 cases, and lobar pneumonia causing death in 4 other cases. In 9 cases the essential symptoms were dyspnea, goitre, cyanosis and edema. These latter cases are of course the one which interest us as clinicians.

In only a few of the cases are recorded accurate data as to the condition of the arteries; when the arteries are mentioned they are spoken of as hard, sclerotic, tortuous. From these data we may draw the picture of arteriosclerosis as follows: A man of forty years or more, though younger cases are seen. Alcohol used to excess. No rheumatism; dyspnea, cough, cyanosis, edema of long standing; enlarged heart, action feeble, irregular and intermittent pulse, murmurs present or not; edema;

trace of albumin with casts. The arteries are hardened, tense, tortuous, and the pulse usually of high tension.

As to treatment, several of the cases had been in the hospital previous to their fatal illness, and had then improved greatly in all respects after the exhibition of digitalis, cathartics, diuretics, and especially rest in bed.

In arteriosclerosis we find, as a rule, a much greater enlargement of the heart than in valvular disease. In 27 cases of arteriosclerosis, out of the whole series of 32, we find that on the average the weight is greater than in diseases dependent upon pathological defect of the valves. Twelve hearts weighed more than 500 grammes, and in 12 instances the heart weighed over 550 grammes, reaching the enormous weight of 800 grammes or more in 2 instances. In only 3 instances did the weight of the heart exceed 550 grammes in enlargement due to valvular disease, uncomplicated by pericarditis.

THE CONDITION OF THE MYOCARDIUM AS AFFECTING CARDIAC MURMURS.*

BY H. D. ARNOLD, M. D., BOSTON.

Physician to Out-Patients, Boston City Hospital; Professor of Clinical Medicine, Tufts College Medical School.

THE importance of the condition of the myocardium in valvular disease of the heart is, I believe, generally recognized by the medical profession. We all know that the gravity of a case depends not alone on the valve lesion itself, but on the extent to which compensation has been established or is capable of being established by the myocardium. Yet the average practitioner is too apt to rest satisfied if, by discovering a murmur, he is able to point out the site of the lesion and can give an anatomical name to the disease. Fortunately for both patient and physician, the heart generally has wonderful recuperative powers, if given half a chance. Rest, with or without medication, — and sometimes in spite of bad meditation, — furnishes the opportunity; and we take credit to ourselves for an improvement which was due to Nature, and neither to our thorough understanding of the condition, nor to an intelligent application of remedies.

If by accurate percussion you determine the area of the heart, if by inspection and palpation you learn its strength and its regularity of action, if you carefully observe the characteristics of the pulse, if you examine the lungs, liver, kidneys, and extremities for evidence of passive congestion, and if you think logically and intelligently about these physical signs and the symptoms learned from the patient, you will understand your case better and treat it more intelligently than if you depend solely or chiefly on auscultation of the heart. And when you auscult the heart it is of even more importance to rightly interpret the cardiac sounds than to detect the murmurs. In fact, an understanding of the condition of the myocardium is the key to the situation.

Nevertheless, the right interpretation of cardiac murmurs is a matter of great importance, and I invite your attention to a consideration of this subject as throwing additional light on the state of the myocardium.

It has been demonstrated experimentally[1] that when fluid confined in chambers or tubes passes through an opening into a wider space beyond, the particles of the fluid are thrown into vibration beyond the opening; and if the force of the current is sufficiently strong these vibrations attain an intensity which enables them to be transmitted to the ear, where they become audible as sound. To this sound we give the name murmur. These are the physical conditions which underlie the existence of a cardiac murmur in most if not in all cases. The vibrations originate in the fluid itself, in the wider space beyond the narrower opening, and are not caused by friction between the fluid and the confining walls.[2] Whether a stiffened valve may be thrown into vibration by the current of blood passing over it, and may thus contribute to the sound perceived by the ear, has not yet been experimentally proven, as far as I know, but the peculiar character of some murmurs and their peculiar path of conduction lead me to suspect that such may be the case.

It has been proved that a murmur may be produced in a straight tube, without any narrowing of the lumen, provided the fluid is forced with sufficient velocity. This velocity, however, is greater than that known to be attained by the circulating blood, and this explanation may practically be disregarded in interpreting cardiac murmurs. A lessened density of the fluid enables a murmur to be produced with less velocity. It is possible that this fact may have something to do with the production of anemic murmurs, but it has not yet been proved that the density of the blood or its velocity in cases of anemia come within the limits required by the experiments.

It is reasonably safe to assume, then, that when we hear a cardiac murmur the blood is passing through some opening into a chamber beyond which has a larger diameter than that opening. A narrowing of any of the valvular orifices presents this condition for the blood in its onward progress. A leakage through any of the valves furnishes the condition in a reversed direction. In the aortic area a widening of the aorta beyond the orifice furnishes the necessary condition, even if the aortic valve is normal. I believe it is the dilatation of the aorta, accompanying arteriosclerotic changes, rather than the roughening of the lining of the valve and blood vessel, which accounts for the frequency of the aortic systolic murmur beyond middle life, a murmur which is so seldom explained at the autopsy by a true stenosis of the aortic valve.

Regurgitant murmurs may be caused at any of the valve orifices without disease of the valve itself, provided the orifice is sufficiently dilated to prevent the proper apposition of the valve curtains. We shall see later that this is a common

* Read before the Boston Society for Medical Improvement, February 4, 1901.

occurrence at the mitral valve. At the aortic valve, however, the tissues surrounding the orifice are so strong that they do not yield readily, and as a rule an aortic regurgitant murmur indicates disease of the valve curtains. Likewise a presystolic murmur at or near the apex indicates disease of the mitral valve, except in the rare instances where it is caused by free aortic regurgitation. What has been said of the aortic and mitral valves applies respectively to the pulmonary and tricuspid valves in the rarer cases in which they are concerned.

Such are the conditions under which cardiac murmurs arise. Their existence always indicates an abnormal though not necessarily a diseased condition. The point of maximum intensity of the murmur and its area of distribution enable us to locate the site of the trouble with some accuracy. In our present enquiry, however, we wish to know what further light murmurs may throw on the cardiac condition.

The loudness of a murmur is not a satisfactory guide to the seriousness of the lesion. Neither is the quality of the murmur. Yet variations in the intensity of a given murmur from time to time may give us information of the greatest value in estimating the condition of the heart. Under these conditions changes in the intensity of a murmur are to a certain extent a measure of changes in the strength of the cardiac muscle. If, with rest and treatment, a weak, dilated heart develops a murmur which was not audible before, or if a faint murmur becomes louder, it is a favorable sign, for it means stronger heart action and implies the beginning of compensatory hypertrophy. The diminution or disappearance of a murmur may also mean improvement, through the removal of the condition causing the murmur, but it may mean a weakening of the cardiac power. The decision lies in the other evidence obtainable, not in the change in the murmur itself. Even organic murmurs sometimes disappear, especially with improvement of the general cardiac condition, and yet the diseased condition of the valve remains. If you have had good reason to decide that a murmur indicated an organic valve lesion, do not give too favorable a prognosis simply because the murmur disappears, and do not conclude that your diagnosis was necessarily wrong. You must, however, be sure that your reasons for calling the murmur organic were well grounded. It does not mean that the valve is diseased, simply because the characteristics of the murmur are marked, nor is it necessarily organic because it lasts weeks or even months.

Mitral murmurs are much more liable to variation and disappearance than are aortic murmurs. Of all cardiac murmurs, the presystolic murmur of mitral stenosis is the most variable. Yet, once definitely heard, it indicates more surely than any other murmur an incurable valvular lesion. Mitral stenosis, moreover, exists more frequently without any murmur whatever than does any other valvular lesion. These peculiarities depend upon the fact that the force which produces the murmur is derived from the auricle, whose action is weaker than that of the ventricle, and perhaps more variable.

Mitral regurgitant murmurs are the commonest of cardiac murmurs, but their real significance is not always as easily determined as in the case of some other murmurs. Of the latter the aortic diastolic and mitral presystolic clearly indicate valvular disease. The aortic systolic usually indicates aortic stenosis or arteriosclerosis of the aorta. All these conditions are incurable, although a stage of tolerance and comfort may be established. I am leaving out the so-called anemic or hemic murmur heard at the aortic area, because it is almost invariably accompanied by murmurs at other cardiac orifices, or by vascular murmurs, or by marked anemia in such a way as to make the condition clear. The prognosis in this case turns on the cause of the anemia rather than on the cardiac condition, and the murmur generally represents a curable condition. Contrasted with these rather definite indications of other murmurs, we find that a mitral regurgitant murmur may be due to an incurable valvular lesion or to conditions which are perfectly curable. The characteristics of the murmur may be the same in both instances. I have found exceptions to every rule laid down for the distinction of organic and functional murmurs at this orifice, provided the rule was based on the character of the murmur alone. We must take other factors into account, and a decision should be formed only after carefully weighing all the evidence obtainable. Is the mitral regurgitant murmur curable, or is it incurable? That is the question raised by the commonest cardiac murmur. The answer is not always easy.

One source of confusion lies in our failure to fully appreciate the difference between the anatomical relations of the aortic and the mitral valves. We are apt to think of them as differing only in the size of the opening and in the number of cusps to the valve. The aortic valve may be described as mechanical and automatic. The cusps are so shaped that they are brought into close apposition with each other by the mere pressure of the arterial blood. They accurately close the opening, and as the thick, fibrous wall of the base of the aorta does not yield readily to pressure, leakage between the cusps from dilatation of the orifice is of relatively uncommon occurrence. Furthermore, the method of attachment of the cusps to the aortic wall, with the corners higher up than the bellying margin, effectually prevents the edge of the cusp from being forced down beyond the orifice. Regurgitation from this cause occurs only with such extreme blood pressure as will tear the valve from its fastenings. This occurs rarely in the strain of sudden extreme muscular exertion.

The mitral valve differs from the aortic in two important respects: (1) There is a less marked development of fibrous tissue at its ring, and the maintenance of its calibre depends to a considerable extent on the cardiac muscle which surrounds

it. It is therefore much more yielding, and is easily dilatable. (2) The mitral curtains, flexible and lying flat in one plane, would not in themselves offer any resistance to the regurgitation of blood through the mitral orifice, whereas the aortic curtains are so attached as to prevent regurgitation. The prevention of this mitral regurgitation depends on the chordæ tendinæ and the papillary muscles, which act as a set of guys to keep the valve curtains from being forced beyond the orifice. The steadiness of the support of these guys depends on the papillary muscles; for the ventricular wall, to which attachment is made, is constantly moving, and would furnish an unsteady support were it not that the action of the papillary muscles just counterbalances that of the ventricular wall. This nice adjustment between the contractile forces of the ventricular wall and the papillary muscles is essential for the perfect closure of the mitral valve, and its practical importance in accounting for murmurs is shown by the fact that it has been demonstrated [3] experimentally that the papillary muscles show diminished power of contraction, as a result of fatigue, quicker than any other part of the cardiac muscle.

More than this, it has been demonstrated [4] experimentally that the size of the normal mitral valve is considerably smaller in systole than in diastole. In other words, the mitral orifice is compressed and narrowed by the contraction of the muscular wall about it during systole, and this narrowing of the mitral orifice is as essential for the perfect closure of the valve as is any other part of the mechanism. The mechanism for the closure of the mitral valve is not, then, automatic in the sense that we used the term for the aortic valve, where the essential factors all lay in the valve curtains themselves. We may say that the closure of the aortic valve is a matter of fibrous mechanism, while the closure of the mitral valve depends largely on muscular mechanism. The one is rigid, the other is yielding in character.

It becomes clear, then, that a weakened action of the cardiac muscle which failed to narrow the mitral orifice sufficiently, or a weakened action of papillary muscles failing to hold the valve curtains firmly, might either one be a sufficient cause for mitral regurgitation. It is probable that both conditions are acting together in most cases. We can thus demonstrate that a weakened or debilitated condition of the cardiac muscle is a sufficient cause for mitral regurgitation, even when no demonstrable dilatation of the ventricular cavity exists, although dilatation will ensue if the weakness is very marked or is prolonged over a long period.

Such regurgitation at the mitral orifice, due merely to a weakened or debilitated condition of the cardiac muscle, is generally curable, because its cause is generally curable. This is true whether dilatation of the ventricle exists or not. If dilatation has existed a sufficiently long time, a cure can be effected only through the development of hypertrophy. The existence of such hypertrophy need not deter us from pronouncing the cardiac trouble cured. For we have assumed that the cause of the trouble is removed; the heart has returned to a condition in which it performs its functions normally; and there is no apparent reason why it should not continue to do so as long and as well as any normal heart. If we must still call it diseased because somewhat hypertrophied, then we must assume that all athletes have diseased hearts, for in them we shall find the heart always more or less hypertrophied. Although, from its frequent association with disease of the heart, we commonly think of hypertrophy of the heart as a pathological lesion, it is rather a manifestation of the normal physiological power of the heart (like any muscle) to develop in proportion to the amount of exercise it performs, provided it is well nourished. It is to be regarded as a pathological condition rather from the conditions with which it is associated than from its mere existence as such. Mitral regurgitation, then, in debilitated or in dilated hearts may be entirely curable if the cause is curable, though the question evidently depends also on the myocardium and its capabilities.

We have been speaking of cases in which the valve curtains themselves were free from disease. Where these are diseased the condition of the myocardium is of equal or even greater importance, for on it the problem of compensation depends. The amount of damage done to the valve is, of course, a very important factor in the problem. Sometimes the damage is so great that compensation is out of the question. At the other extreme lie the cases in which the post mortem examination shows that an old endocarditis has left some traces of its existence on the valve curtains, but of such slight degree that there is no evidence that they were incompetent, and clinically no evidence of heart trouble existed. The occurrence of these lighter cases brings up the question whether a mitral regurgitant murmur may accompany endocarditis and yet represent a curable condition.

Before answering this question, we must consider the significance of the systolic apex murmur so often heard in acute rheumatism. Does it always mean endocarditis? Does it always mean mitral regurgitation?

When I was a medical student, I was taught that oftentimes the only evidence of an endocarditis in an attack of acute rheumatism is to be found in a systolic murmur at the apex of the heart. This is undoubtedly correct. I was also taught that such a murmur arising in the course of acute rheumatism means endocarditis. This view I have come to consider incorrect. The murmur often does mean endocarditis, but not necessarily.

I find a foot note in my textbook of that time wherein my instructor stated that when this murmur does not exhibit the characteristics of mitral regurgitation, it is to be considered an example of Flint's "Mitral Systolic Non-regurgitant Murmur." This is described by Flint [5] as a systolic murmur, heard within a limited area at the apex,

arising within the ventricle and not at the mitral orifice, and due to the roughness of the endocardial membrane and not to mitral incompetence. Flint says this "is the murmur present in endocarditis." He adds significantly: "This murmur cannot always be discriminated from a feeble mitral regurgitant murmur."

Careful analysis of this view shows that it is based entirely on the area of distribution of the murmur. Because it has not the classical distribution of a mitral regurgitant murmur, namely, to the left axilla and perhaps to the angle of the left scapula, it is argued that it cannot be due to mitral regurgitation, and another theory must be advanced to account for it. The first premise of this argument is wrong. Even a cursory examination of the area of distribution of mitral regurgitant murmurs shows that it may vary widely from the classical description. It need not necessarily be transmitted as far as the axilla. Furthermore, the explanation offered, that it is due to the blood passing over the roughened endocardium, is much less probable than that a mitral regurgitant murmur should have a limited area of distribution. This attempt to account for the murmur is a leap from the frying pan of difficult, but possible, explanation, into the fire of well-nigh impossible theory. For the weight of experimental evidence is against mere roughening of the wall as an adequate explanation of a murmur by friction between the fluid and the wall; and the velocity of the blood within the ventricle itself, before it is forced through the narrower opening of the aorta, is too slight to account for the murmur in any other way. I believe we should distinguish between the facts in cardiodynamics, which have been proved by pathological demonstration and by physical or physiological experiment, and the theories which, though originating in the imagination of some of our greatest medical minds, form an insecure and unreliable foundation on which to base our knowledge of cardiac disease.

The confusion of theory and fact in our mental processes is a serious fault of much of our medical thought; it explains much of our loose and illogical methods of reasoning, and is responsible in part, I believe, for the cloudiness which involves some of the questions of cardiac physics. Because some cases of rheumatism have endocarditis, and because some systolic murmurs at the apex indicate endocarditis, we are too apt to draw the illogical conclusion that in rheumatism all systolic murmurs at the apex mean endocarditis. We forget that the autopsy sometimes fails to confirm this view, and we forget that a systolic murmur with the same characteristics is often found in other diseases, which are not prone to develop endocarditis. These other diseases have, in common with rheumatism, a toxic state of the blood, fever, and general prostration — conditions under which weakness of the cardiac muscle is apt to develop, and in which, therefore, mitral regurgitation may occur without endocarditis or any affection of the valve itself. Many of the systolic apex murmurs heard in rheumatism are, I believe, due to the muscular weakness and relaxation from these causes and not to endocarditis. The indication for treatment is the same in both cases; the need of watchfulness to detect this condition of the myocardium is as great in cardiac weakness as in a mild endocarditis, but the prognosis is different. The lesson to be learned from this view is not that we may neglect watching for murmurs in rheumatism because they may be less serious than we supposed, but that a state of the myocardium as bad as often exists in rheumatism exists in other infectious febrile diseases, and that we should watch the heart as closely in these diseases as we have been taught to do in rheumatism.

With reference to the diagnosis of endocarditis from the murmurs in rheumatism, I wish to quote what Gibson says:[6] "On auscultation there are great possibilities of error. In all febrile conditions, such as so often lead to endocarditis, the heart is apt to undergo dilatation, and not only is there a change in the cardiac sounds, but systolic murmurs are extremely common at the auriculoventricular orifices, along with accentuation of the pulmonary second sound. Such murmurs may obviously be caused by changes in the cardiac walls, or in the papillary muscles, and therefore have no necessary connection with endocarditis; as has already been remarked, reliance upon these murmurs as an indication of endocarditis has rendered most clinical statistics connected with the subject open to the gravest suspicion. It cannot be urged too strongly that the only absolute diagnostic means consists in the appearance of murmurs of obstruction at one or the other of the orifices." . . . "The determination of the probable condition in any given case can only be attained by carefully weighing the whole evidence available, and the possibility that murmurs of incompetence at the venous valves may be due to acute myocarditis must not be overlooked."

We can now answer the questions which we propounded about the systolic apex murmurs in rheumatism. They are not necessarily due to endocarditis. They do mean mitral regurgitation, but not necessarily a diseased valve. As to the question whether a mitral regurgitant murmur may represent a curable condition if accompanying endocarditis, it is conceivable that it may, for we have seen that the amount of endocarditis may be too slight to make the valve incompetent, and yet an accompanying muscular weakness might allow the blood to regurgitate. This condition, however, we cannot distinguish clinically from a case in which the murmur is due to incurable endocarditis, nor from one where we have only muscular relaxation without any endocarditis. Time alone will solve the whole problem of these mitral regurgitant murmurs, and an absolute decision as to their curability should be reserved. More or less probability we may attain by a consideration of all the circumstances, and of these the most important is the condition of the myocardium.

We have been considering mitral regurgitation with reference to its ultimate curability or incurability. This is not the whole problem, for in the

incurable cases we may attain a condition of relative health of the heart which will last for a longer or shorter time — perhaps for years. Whether in an acute attack or an exacerbation we can attain this condition of compensation depends entirely on the capacity of the myocardium.

We have still one class of cardiac murmurs to consider — the so-called functional murmurs. The best definition of a functional murmur is that it is not organic. A murmur due to a physical change in the heart, like valvular disease, is called organic. We can account for it satisfactorily by demonstrable physical change. When we cannot so account for the murmur we call it functional — and then begin to invent theories to explain its occurrence. As we did not find the heart diseased, we theorize that the trouble lies in the blood, but we deceive ourselves if we think we have added anything but an unproved theory to our knowledge by calling it a hemic murmur. When anemia is present we call it an anemic murmur — but that explains nothing. It may yet be proved that such occurrences are caused by some condition of the blood, but in the meantime let us confess that by a functional, hemic or anemic murmur we really mean a murmur which we cannot satisfactorily explain.

In anemia we have a most confused state of affairs as to the murmurs. Anemia is supposed to furnish the most typical examples of purely functional murmurs, and yet many of the murmurs are as clearly organic as in valvular disease. It is well known that in severe anemia the heart may become dilated, and in fatal anemia we may find extreme fatty degeneration as well as dilatation. Murmurs due to these conditions are clearly organic. In less marked conditions the murmurs are generally admitted to have all the characteristics of mitral regurgitation. If there is dilatation, the explanation is easy, and the murmur is a mitral regurgitant murmur and is organic. If there is no demonstrable dilatation it is still mitral regurgitation, I believe, due to the fact that in anemia the heart muscle is poorly nourished and weak and the muscular part of the closure of the orifice is imperfectly performed.

The next grade is where the murmur is systolic but has not the classical distribution of mitral regurgitation. Then comes the grand dispute about anemic murmurs. Because generally [7] heard best at the left base of the heart, they are ascribed to the pulmonary artery. Then the fact that there is no change at the pulmonary orifice is adduced to prove that the trouble lies in the state of the blood itself. The point of maximum intensity is quarrelled over to the fraction of an inch, and then every one admits that it is frequently heard loudest somewhere else.

The trouble lies, it seems to me, in the attempt to gauge these anemic murmurs by imperfect standards. We do not as yet fully understand the path of conduction of murmurs, nor the area of distribution, yet these are the means by which we try to determine where a murmur originates. Until our knowledge on these points is clearer, we should not attempt to dogmatize.

I have spent some little time studying cases of this [8] sort, and two things have been impressed upon me. One is that murmurs which I had every reason to suppose were from mitral regurgitation often had the point of maximum intensity higher up than the apex, along the left border of the heart, and might have an irregular distribution on the chest wall. The other was that I found in anemia murmurs showing every gradation in area of distribution from a clearly recognized mitral regurgitation to what is usually called a typical anemic murmur in the second left interspace. Where shall we draw the line? When do we cease to have mitral regurgitation as an explanation? I am not at all sure that we do. I am inclined to the belief that all the anemic murmurs on the left side of the heart are really due to mitral regurgitation, showing various areas of distribution according to the means by which the vibrations travel from the left auricle to the surface.

This view is as yet far from proven. It is only a working hypothesis. I would prolong the paper too much to attempt to discuss further the reasons for this view. But this much may be said confidently of the anemic or other functional murmurs; that, whatever their cause, the important thing to understand is the state of the myocardium. Is the heart dilated? Is its action strong or weak? These are the essential features to learn, and the conditions that determine treatment.

Whenever a murmur exists, then, it is of great importance to investigate the condition of the myocardium. By so doing we may find the cause of the murmur in an entirely remediable condition of the cardiac muscle, and we may save ourselves the mortification of ascribing it to incurable valvular disease, and we may spare our patient from a life of worry and dread which the latter diagnosis so often inspires. Whether the disease be curable or not, we find in the condition of the myocardium fully as important data on which to base prognosis as is found in the cardiac murmurs. The existence of a murmur gives us in itself little aid in determining the proper line of treatment. That is determined by other factors, chief among which is the condition of the cardiac muscle. Let us not, then, rest content with an examination of the heart for murmurs. That is important, of course. If discovered they throw valuable light on the diagnosis and, to some extent, on the prognosis. But when we have done so much we have only begun the investigation — not ended it; we have only learned that there is something about the heart to investigate; let us investigate it thoroughly, with every means at our command.

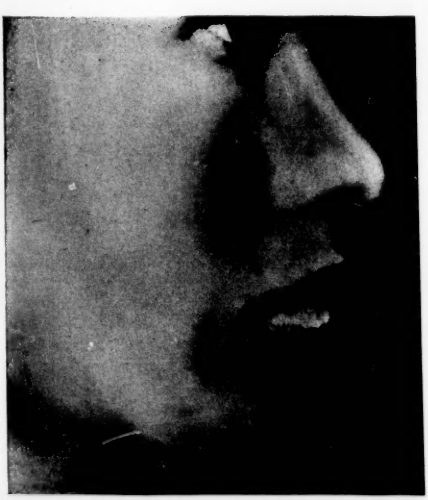
FIG. 1.—Epidermoid cancer of the lip before treatment by the x-rays.



FIGS. 2 and 3.—Cuts of photographs taken directly after healing. The induration had wholly disappeared; the lip where the growth had been was without scar and perfectly smooth and soft; it was a little wider on the right side, otherwise there was nothing abnormal in its appearance. Some weeks later this increase in width had diminished so that the cosmetic result was perfectly satisfactory, even better than is shown in the cut. The patient shaved off his moustache the day before the photographs from which these cuts were made, were taken.

A FURTHER NOTE ON THE TREATMENT OF EPIDERMOID CANCER.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

In a note published in this journal January 17, 1901, I stated that I had treated cases of epidermoid cancer by exposure to the radiation from an excited Crookes' tube, and that these cases had yielded to treatment without accompanying or subsequent pain or irritation.

The results produced by this method of treatment are seen in the accompanying cuts, which are taken from my forthcoming book on the uses of the Roentgen rays, by permission of The Macmillan Company. The photographs were made from one of the patients, whom I presented at the meeting of the Medical Society of the Boston City Hospital, in February last. The diagnosis of epidermoid cancer in this patient was confirmed by Dr. Mallory, pathologist at the Boston City Hospital, to whom a small piece of the growth was submitted. Fig. 1 is a cut of the photograph which was made before exposure to the x-rays; Figs. 2 and 3 from photographs taken after treatment. The induration on the lip extended beyond the affected area shown in the half-tone. The gland under the inferior maxilla, to the right of the symphysis, had been enlarged; but the enlargement disappeared after the lip had healed.

The exposure to the rays lasted usually five minutes, and was given nearly every day for some weeks, but further experience has suggested that so long a period of treatment is unnecessary. The cuts here presented were taken from the smallest growth that I have treated.

This patient, together with others, demonstrated, as I have previously stated, that we have in the radiation from an excited Crookes' tube, in all probability the x-rays themselves, a therapeutic agent which is of value in the treatment of at least superficial cancer in its early stage, and that healing takes place without any caustic action.

In some of my patients the treatment, given nearly every day, was stopped after improvement had well begun; in one patient the treatment given at intervals of a day or two was stopped after a few exposures only, but in all of these cases the improvement steadily continued without renewal of treatment. From this I infer that the rays interfere, probably directly, with the life, whatever it may be, which causes the cancer. Further, as this is accomplished without much difficulty in superficial growths, penetrating to a depth of two centimetres at least, it gives ground for hope that something may be done for patients in whom the disease is deeper seated.

Clinical Department.

REPORT OF CASES FROM THE SECOND SURGICAL SERVICE OF THE CHILDREN'S HOSPITAL, BOSTON.

BY H. L. BURRELL, M.D., R. W. LOVETT, M.D., AND J. E. GOLDTHWAIT, M.D., BOSTON.

CASE I. MULTIPLE PLEXIFORM FIBROMATA.

S. M., age ten years, entered the hospital November 7, 1899. Her mother was a prostitute, who probably had syphilis. Her father was a mulatto, who died of phthisis. The child was adopted when small. Since then she has had no children's diseases, but has had trouble with her eyes and has had sores about the anus. For seven years she has had increasing swelling and stiffness of left leg. Some pain has accompanied this trouble.

Examination showed a well developed and nourished girl. Her skin presented numerous yellow patches varying from ¼ to ¾ inch in size. And about the anus was more or less scar tissue. Glands were found in both groins. The left knee presented a fusiform swelling, involving the thigh and calf. Some bony thickening of the knee existed, and there was some limitation of motion. A large tumor mass with hard kernels in it involved the popliteal space and pressure over the mass elicited some pain. The left leg was 3 inches longer than the right. The left knee was 4 inches and the left calf 1¾ inches greater in circumference than the right. The left thigh was ¾ inch smaller than the right. The right foot was in an equinus position (Fig. 1).

The child was given iodide of potash, so that by November 20th she was taking 30 grains three times daily. This was omitted December 6th.

December 1st. The patient was etherized and an Esmarch bandage and a tourniquet were applied, the legs being measured both before and after. The measurements of the left leg were considerably lessened after the application, the knee diminishing 1 inch in circumference. The measurements of the right leg were barely altered. On December 12th an incision was made on the outside of the middle of calf and some of the hard masses that had been felt were removed for diagnosis. These were "found to consist of small kernels, resembling sago, in a network or stroma." On December 23d the iodide of potash treatment was started again, increasing doses being given. By January 30, 1900, 150 grains were given daily. On February 10th the iodide was stopped.

On February 28th an incision was made on the inner side of calf, and a dissection was carried

through the superficial fascia and a mass of translucent tissue was removed from between the muscles and about the vessels. The mass was encapsulated as it could be shelled out of its bed. The whole of the mass was not removed, owing to its extent, but the child improved and was discharged relieved on March 21, 1900.

The tissue which was removed was examined by Dr. R. M. Pearce. His report is as follows:

BOSTON, February 28, 1901.

Tissue to be examined consists of fascia, muscle and connective tissues of leg. Throughout the mass are seen small, firm, round or oval, glistening bodies. Upon dissecting the mass these bodies are found to be small tumor masses apparently developing about nerve

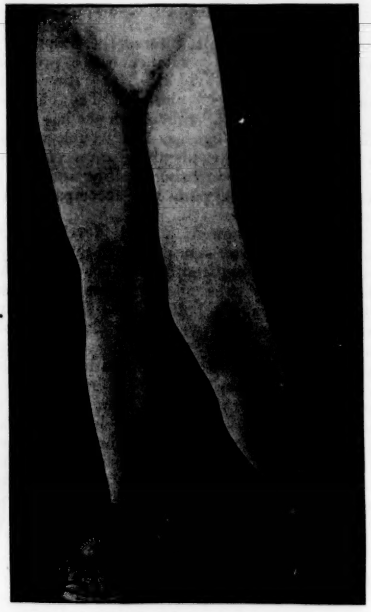

FIG. 1.

bundles, the whole forming a plexiform network with varicosities. These masses are exceedingly firm and opalescent, often spindle-shaped, varying in circumference and covered by a thin capsule. They lie principally in the intermuscular septa (Fig. 2).

Diagnosis. — Multiple fibromata of nerves.

R. M. PEARCE, M.D.

This case belongs to the class described in the literature as neuroma cirsoideum, plexiform neuroma, or Ranken neurom. Many of these cases are evidently described clinically as congenital elephantiasis — congenital hypertrophy[1], etc. The growth is a rare one, but so striking and unusual in character that cases are reported, and since Bruns in 1870 gave the first competent description, some 40 to 50 cases are on record. Bruns[2] himself in a later paper tabulates 42 cases.

A recent paper by Preble and Hektoen[3] gives the summary of reported cases as well as the report of a case with autopsy.

The growth under consideration is even clinically characteristic. If the tumor is single it may be of any size up to the largest; is apt to be flattish in general form with or without overhanging sacklike edges, and it is often lobulated and the skin over it apt to be adherent and changed in character. It may have an increased hair growth, and is often pigmented with brownish mole-like pigment. On palpation the tumor as a whole is soft, usually not adherent to deeper structures, and fairly movable to the touch and is of uneven consistency, and on manipulation suggests the worm-like feel of a varicocele, save that the individual

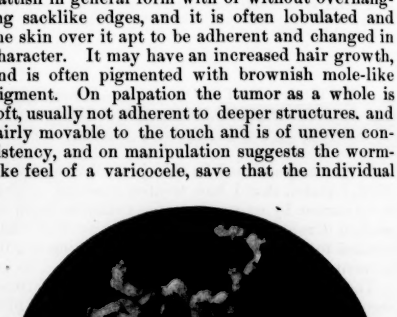

FIG. 2.

cords in this case are of hard, tough consistency.

The most usual site of the tumors is, according to Bruns, the temporal region or the head and nape behind the ear. They may, however, appear on the back, trunk, face, arms, legs, or even as sacral growths, or in the perineum. As a rule there is not more than one conspicuous tumor, but in the majority of cases other growths are to be found under the skin, often irregularly following nerve trunks, or actually showing as rosary-like beadings along the nerves themselves. The tumor may lie beneath as well as above the fascia. Pomorski records a case where the pleura was invaded from without, or they may form an elephantiasis consisting of an actual tumor formation about the distribution and endings of the skin nerves over a considerable area. The growths may involve the deeper plexuses (solar plexia: Robin: mesenteric nerves: Hektoen), or they may invade

[1] So for example a case by Jonan, Rev. d'orth, January, 1900, p. 61, described as hypertrophy apparently belongs here.

[2] Beitrage z. kl. chir., viii, 1891-1892, p. 1.

[3] American Journal Medical Science, January, 1901, p. 1.

the spinal canal along the nerve roots (Hektoen), or even exist within the cranium (Berggrün). In cases with these multiform multiple tumors there are likely to be associated with them both scattered pigmentation (as in the present case) and skin tumors of the sort known as fibroma molluscum long since shown (Recklinghausen, 1882), to be actually neurofibromata.

Surgically, the growth is usually reasonably well limited, mobile, and vascular.

Pathologically, the whole series — Ranken-neurom, general neuromatosis, fibroma molluscum or congenital elephantiasis — have one basal structure, and differ only in the place and arrangement of their growth. They consist of fibrous growth of the nerve sheaths about the nerve endings of smaller or larger nerves, penetrating between and enclosing the nerve fibres, and often causing their entire atrophy. The growth increases by concentric increase in size or by invasion along previously unaffected nerve trunks, but only in this way. It has nothing, really, in common with the sarcoma, but belongs to a sort of neuro- and fibromatous diathesis, manifesting itself at varying periods, but often, as Bruns has conclusively shown, is of hereditary origin, apparently (usually at last), fatal in character, and declaring itself in one way or another at birth or in very early life.

The growths *per se* cause no symptoms, and curiously enough almost no interference with nerve function except when they invade spinal canal or cranium, which is excessively rare. They are important through the deformity and inconvenience, and through the late danger of sloughing and sepsis. The prognosis of spontaneous cure is very slight, though individual tumors may decrease or disappear. H. L. B.

CASE II. PARAPLEGIA EXISTING FROM BIRTH; LAMINECTOMY AT THE AGE OF FIVE AND ONE-HALF MONTHS.

X. Y., who was five and one-half months old, was admitted to the hospital May 4, 1900, for a paralysis of both legs, existing since birth. The labor had been a difficult one, inasmuch as placenta previa existed and delivery was performed by rapid version. The version was performed by a skilful obstetrician, who was present in consultation.

After delivery the child progressed favorably, but when two or three weeks old it was noticed that it did not move the legs. There was at no time soreness of the back, or pain at being lifted, and nothing abnormal in the spine was noticed by the parents or nurse.

When it was a few weeks old the child was seen by one of the surgical staff of the hospital, and a neurologist was called in consultation. The examination showed apparent abolition of reflexes in the lower half of the body, together with a disappearance of sensation and motion nearly to the level of the umbilicus. There was some swelling of the legs, and the child, although well developed and healthy in other respects, was somewhat nervous, starting in its sleep and giving signs of undue nervous activity. The bowels were constipated, the bladder had little or no power of retaining urine, the back was normally movable, and there was no undue prominence anywhere, or evidence of anything wrong, with the exception of a slight fullness in the lumbar region.

In the hope of contributing something to the diagnosis and possibly demonstrating the existence of incomplete spina bifida, the child was chloroformed and an x-ray photograph taken, which showed nothing abnormal in regard to the bony structure of the spine. An unfavorable prognosis was given, and it was decided that the affection was probably not traumatic, but more probably some congenital malformation.

The child did not improve, and at the age of five months the parents were told that an operation offered some slight prospect of relief, in case there was anything pressing upon the spinal cord. The operation was not advised, but the parents were told that it was perfectly proper that it should be done if they so wished. Inasmuch as they knew that the prognosis was definitely bad, the parents were desirous of having the operation performed.

The child was admitted to the hospital on the 5th of May, 1900. She was etherized, and a straight incision made at the dorse lumbar junction, and the spinous processes of three laminæ removed, the site of the operation being located by the neurologist. The spinal canal was opened without difficulty and considerable fatty tissue was found outside of the dura. The dura was opened and much clear fluid escaped, a surprising amount welling up from the wound and flowing off at the sides. A director was passed up and down the spinal canal to see that there was no pressure existing, and the nerves coming off from the spinal cord appeared to be small and adherent to the dura. So far as it seemed proper the nerves were freed from the dura, the dura was left open, and the muscles and skin were sewed up separately. No evidence of traumatism existed and the condition seemed to be a congenital deficiency or malformation of the spinal cord. The spinal cord itself looked very small, but of course one could not say that it was more than relatively so.

The child made a perfect convalescence; there was little or no rise of temperature, and at the end of a week it was sent home with the wound healed. The swelling in the legs immediately diminished, and the child's nervous irritability disappeared. In two weeks it was distinctly better than before operation. There has, however, been no further improvement; the paralysis continues and the swelling exists in a moderate degree. R. W. L.

CASE III. A CASE OF UNUNITED FRACTURE OF THE FEMUR IN A CHILD IN WHICH THE NON-UNION WAS DUE TO THE FORMATION OF A CYST AT THE ENDS OF THE FRAGMENTS.

A girl, eleven years of age, having been previously well, in May, 1900, was run over by a wagon and the right femur broken at about the

middle of the shaft. She was under careful treatment for thirteen weeks, after which she was allowed up, the leg being straight, but a lump on the middle of the thigh was noticed by the mother. The child had been able to move about freely with the aid of crutches, leaning some weight upon the leg, but the mother is confident that the bunch in the middle of the thigh had gradually increased. In the middle of October the leg gave way and the child fell to the sidewalk.

One week later she was brought to the Children's Hospital, with a definite fracture in the middle of the shaft of the femur, and with ¾ of an inch shortening of the right leg, the shortening all being between the anterior superior spine and the inner condyle of the femur. Aside from this condition the child seemed well. The x-ray examination revealed an ununited fracture with overriding of the fragments. Traction in bed was attempted, but after several days there was no increase in the length of the leg. Ether manipulation was then attempted, but even though considerable force was used it was impossible to bring the fragments into the correct position. After one week more of trial of bed treatment without result, the patient was operated upon, and at the seat of the break a swelling as large as a lemon was found which contained about an ounce of clear, straw-colored fluid. The fluid was under so much pressure that when the cyst was punctured it spurted for several feet. The wall of the cyst was made of a thin, hard and brittle substance, which the pathologist reported to be bone callus. All of this wall was removed, the edges of the bone refreshed and brought together, the wound closed and traction and coaptation splints applied. Seven weeks later there is no yielding at the seat of fracture, the length of the legs is exactly the same, and the healing has apparently gone on without any departure from the normal course.

J. E. G.

Medical Progress.

RECENT PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

(Continued from No. 13, p. 313.)

FOOD AND DRUGS.

Inspection of American Meat.[13]

The number of live cattle intended for slaughter inspected by the U. S. Government in 1900 was 53,087,994. Every case of preserved canned beef exported from the canneries of the Great West, bears evidence of official inspection, and therefore proof that the contents of those cases were taken from sound and healthy animals. Consideration of the facts and figures presented suggests to meat inspectors everywhere that the Americans are fully alive to the value of the great demand which they have created in Great Britain for their meat products. The New Zealand Government is about to adopt inspection of all meats which are exported from that colony. It is well to know that the United States have for many years past inspected the meat they have used at home and supplied to England.

The Hygiene of Bread Manufacture.

Drs. Waldo and Walsh[14] suggested two methods by which a loaf of bread might convey specific organisms capable of causing injury to consumers.

(1) Organisms that have lodged on the crust of the loaf from surface contamination in an infected bakery; (2) organisms that have possibly escaped destruction in the interior of the loaf during the process of baking.

The authors carried out a series of experiments to determine the second of these possible modes of infection.

Experiments upon temperature:

(1) There is an average temperature in the middle of an ordinary quartern loaf of 75° to 86°C. (163° to 187°F.), and in smaller loaves of 86° to 95°C. (187° to 203°F). (2) There is a steady increase in the temperature in the middle of a loaf during the baking. The highest of these temperatures are only maintained for a short time, and are not high enough nor maintained for a sufficient time to destroy all bacilli and their spores.

Loaves were obtained from different bakeries in London, and examined by direct microscopic examination and by cultivation. The former method proved unsatisfactory, while the latter under two methods of examination yielded thirteen species of bacteria from 62 loaves of bread. These were non-pathogenic organisms. The authors argued that if these could survive the heat of baking, certain pathogenic forms might pass the same ordeal.

In a later chapter (page 41) the statement is made that the cholera bacillus has been cultivated from bread made of dough infected with a pure culture of that organism. (This subject is worthy of further investigation.)

Pathogenic Microbes in Milk.[15]

The medical officer of the London County Council caused an examination of London milk to be made last year, with the following result:

These samples were taken by an inspector in sterile glass-stoppered bottles from milk churns sent from country farms to the principal stations in London, before being handed over to the agents. Immediately after filling, the bottles were carefully stoppered, sealed, tied and brought directly to the laboratory. The bacteriological analysis was undertaken chiefly with the view of seeing whether or not any sample of the milk contained the tubercle bacillus, but during the inquiry some other microbes were detected now and again, which on account of their specific pathogenicity to animals, at any rate, deserve consideration.

[13] British Food Journal, February 1901, p. 51.

[14] Bread, Bakehouses and Bacteria, London.

[15] The Journal of Hygiene, vol. 1, No. 1, January, 1901, p. 78.

(1) Seven per cent. of the samples of "country" milk produced typical true tubercle in the guinea pig; (2) 8% of the samples of "country" milk produced typical pseudotuberculosis (non-acid fast bacillus of pseudotuberculosis. — A. Pfeiffer.); (3) 1% of milk samples produced diphtheria in the guinea pig, yielding the typical true bacillus diphtheria; (4) 1% of milk samples caused a chronic disease (in most cases with fatal results) due to a pathogenic torula apparently differing in cultural and physiological characteristics from the torula (pathogenic blastomycetes) obtained by Sanfelice, Plimmer and others, from human cancer; (5) out of the secretions of the cow's udder two pyogenic microbes were obtained: Bacillus diphtheriodes and streptococcus radiatus (pyogenes).

Death Due to Lead in Beer.[16]

A case is reported which occurred in Glamorganshire, England, of a fatal case of lead poisoning from the following cause: A workman, who went to his work early in the morning, drank each morning a glass of beer at a certain public house, receiving beer which had been in contact with lead pipes over night. The patient died, as was believed, of lead poisoning. A sample of this beer gave abundant evidence of the presence of lead.

Effect of Food Prepared with Alum Baking Powder upon Digestion.

Dr. E. E. Smith[17] reports the results of experiments made to determine the healthfulness of alum baking powders.

The first set of experiments was made to determine the influence of this food on secretion in the stomach. Test breakfasts of baking-powder bread and control bread were given to healthy individuals. The contents of the stomach were withdrawn an hour afterward and examined for acid and pepsin.

A more elaborate experiment was conducted to determine whether the baking-powder bread was absorbed from the digestive tract to the same extent as the control bread, and whether, in the process of digestion and absorption, there was any evidence of disturbing influence. The procedure was based upon the method for determining the co-efficient of availability of a dietary.

The result of these experiments was that food prepared with alum baking powder did not interfere with gastric secretion, and that it was utilized by the body in the same way and to the same extent, as other bread. The investigation revealed no reason for believing such food at all injurious or unwholesome.

Royal Commission on Beer Poisoning.[18]

A Royal commission of six persons has been appointed with the following instructions:

To ascertain with respect to England and Wales. (1) The amount of recent exceptional sickness and death attributable to poisoning by arsenic.

(2) Whether such exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, and if so (*a*) to what extent; (*b*) by what ingredients, or in what manner the arsenic was conveyed; and (*c*) in what way may such ingredients become arsenicated.

(3) If it is found that exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, by what safeguards the introduction of arsenic therein can be prevented.

NOTES UPON THE GERMAN LAWS[19] RELATING TO THE SALE OF PROPRIETARY MEDICINES.

The following comments upon the German laws relating to the sale of drugs, are worthy of notice, and in many particulars such laws might be copied in America.

The statutes have only forbidden the trade in and the sale of unapproved remedies. Private individuals may order them from foreign countries. (Ministerial Rescript of 1842.)

Since the effort to increase one's income by illegally advertising remedies which in themselves are worthless, but are recommended for a host of diseases, has greatly increased, these preparations should be suppressed as a measure of public welfare. Therefore, not only requests for the right to prepare and sell secret remedies, although shown to be harmless, will be denied, but concessions granted exceptionally in previous years, must expire with the decease of the persons to whom they were granted, and are not to be transmitted to others. (Rescript of October 12, 1867).

All advertisements or private announcements of proprietary medicines, of whatever name are forbidden, and offences will be punished according to Article 83 of the Code. Similar action can be taken by the local police. (Rescript of February 20, 1885.)

For the purpose of suppressing the growing evil of proprietary preparations, the Royal Police Board in Berlin causes such remedies to be analyzed by experts with reference to their constituents, and also with reference to their actual cost, and if necessary obtains information as to their manufacturers. A criminal suit may be founded upon the results of this investigation, under Section 367 (3) of the Criminal Code. In case of a successful suit, the composition of the remedy, its actual value, its healing qualities, and under certain circumstances the previous life of the manufacturer, may be published, and the community may be warned against purchasing it.

These precautions, and especially the injunction and the warning given to the public have had a very beneficial effect in Berlin.

On the other hand, in consequence of the vigorous application of these regulations in Berlin, the manufacturers, hard pressed by the police authori-

[19] Die Apotheker Gesetze, nach Deutsch. Reichs, u. Preussischen Landes-Recht. W. Staas, Berlin.

ties, have carried on their business and plundered the people in the outlying districts.

HYGIENE OF INFANTS AND SCHOOL CHILDREN.

The Teeth of School Children.

Spokes [20] gives the following figures as the result of examination of 10,500 English and Scotch boys and girls of an average age of twelve years: These children had 37,000 unsound teeth. There were 18,000 decayed temporary teeth, more than half of which should have been filled. There were 19,000 permanent teeth, 13,000 of which should have been saved, and 6,000 required extraction. Only 14% had teeth free from decay.

The Eyes of School Children.

Butler states that (1) Refractive errors are extremely common among school children, being present in as many as 50%. (2) These errors are of great importance, on account of the immediate symptoms and disabilities which follow their neglect. (3) They are important factors in the production of many painful and disabling affections. Common enough in children, but still more so in adult life. (4) This early correction is demanded not merely as a means of therapeutics, but as an important measure of preventive medicine.

The Inability of Mothers to Nurse Their Offspring.

Von Bunge [21] presents the results of an investigation in which he shows that the increasing inability of mothers to nurse their infants is a matter of inheritance.

He obtained information relative to 665 cases with the following result:

The *daughter* was *able* to nurse her offspring in 182 cases. The *mother* was *able* in 99.2% and *unable* in only 0.8%. The *mother* was able in 237 cases. The *daughter* was *able* in 53.2% and *unable* in 46.8%.	The *daughter* was *unable* to nurse her offspring in 483 cases. The *mother* was *able* in 43.2% and *unable* in 56.8%. The *mother* was *unable* in 147 cases. The *daughter* was *able* in 0.7% and *unable* in 99.3%.

He concludes from the foregoing figures that inability to nurse is largely a matter of inheritance. Further inquiries also led him to believe that tuberculosis and nervous diseases were to a considerable extent associated with inability to nurse one's offspring.

But much more prominent appears to be the relation of intemperance. Where the mother and daughter were both able to nurse he found that the fathers were usually, at least, moderate in the use of alcohol, and only in 4.5% were they hard drinkers. On the other hand, when the mother was able to nurse, but the daughter was unable, it was found that the father was often intemperate and in 46.8% was an actual drunkard.

In this inquiry the author considered those only as able to nurse who could nurse all their children for a period of nine months, and all others as unable.

Infant Hygiene.

Dr. Charles Porter,[22] in a paper on the teaching of "Infant Hygiene," showed that the chief causes of infant mortality in his city (Stockport) were, in the order of their intensity: (1) Diarrheal diseases and the effects of malnutrition which together are responsible for 50% of such deaths; (2) respiratory diseases; (3) prematurity at birth. "But the mere number of deaths of infants is a very inadequate expression of the evil wrought by the conditions responsible for them. The wholesale rejection in manufacturing districts of war volunteers has made it conspicuously evident that the survivors of an unhealthy infancy too frequently develop into puny and physically deficient adults. From the recent analysis above referred to, I have no hesitation in saying that more than half the infant deaths in Stockport and a corresponding proportion of non-fatal damage to child life are (in the words of Herbert Spencer) the result of 'unreasoning custom, impulse, fancy, joined with the suggestions of ignorant nurses, and the prejudiced counsels of grandmothers.'"

Impressed with the gravity of this matter and having long and carefully considered the various means suggested for checking this evil, and especially the provision of crèches (which when established are often strangely unpopular or ignored) the Sanitary Committee became increasingly convinced that there is no royal road to improvement, and that any change for the better must be commensurate with the spread of knowledge of infant hygiene amongst mothers and those who, in the natural course of events, will become mothers. Accordingly it was decided to circulate twice yearly, a handbook of suggestions as to the "Feeding and Care of Infants." It was further resolved to invite the co-operation of the school teachers, and to offer prizes for competition in each school undertaking to impart such instruction to the older girls.

The appointment of a female sanitary inspector was also recommended, whose duty it should be to visit houses in which there were newly born infants, and give directions as to their care and inquire as to the cause of infant deaths.

Infant Life Protection.[23]

The *Local Government Chronicle* (England) makes the following just comments upon the Infant Life Protection Law, enacted by Parliament in 1897, and upon certain professed amendments now being considered for further legislation:

The act of 1897 was a tentative act, and it was apparently believed by its framers that it would be sufficient — in the first instance, at any rate — to deal with wholesale baby farming, and to leave retail baby farming to take care of itself. Experience has shown that, as a matter of fact, the retail baby farming trade requires to be supervised quite as much, if not more, than the wholesale trade. At present, inspectors under the act may

[22] Public Health, February, 1901, p. 344.
[23] Local Government Chronicle, March 2, 1901.

intervene if they find more than one farmed-out infant under five years of age kept in any house or premises which are so unfit or overcrowded as to endanger their health, and may obtain orders for the removal of the children to the workhouse or a place of safety until the children can be restored to their relatives or guardians, or otherwise lawfully disposed. By the bill it is proposed to extend these powers to children boarded out singly. It is not easy to see what valid objection can be raised to this extension of the principal act. It is also proposed to extend the age for the supervision of the children to whom the act applies from five to seven years. This also seems to us to be an unobjectionable proposal. The remaining proposal is to make the act apply in the case of all children under two years of age who are farmed out in consideration of a lump sum, whatever the amount of the lump sum may be, where no agreement has been made for any further payment. The act at present applies to these children only in cases where the lump sum does not exceed twenty pounds. It is very difficult to defend this limitation. Whatever the lump sum may be, it is equally to the interest of the person receiving the child that its life should be as short as possible, if it is clear that no further payments will be made in respect of its maintenance.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M. D., SECRETARY.

Regular meeting, Monday, February 4, 1901, Dr. E. H. Bradford in the chair.

Dr. Henry Jackson read a paper entitled

DISEASES OF THE MYOCARDIUM.[1]

Dr. H. D. Arnold read a paper on

THE CONDITION OF THE MYOCARDIUM AS AFFECTING CARDIAC MURMURS.[2]

Dr. H. F. Vickery: The extent and thoroughness of the papers which have been read to-night makes it, it seems to me, almost impossible to discuss them in any true sense. With regard to the study of the heart muscle there are two things which have struck me. One is that a heart which proves upon autopsy to be badly degenerated may beat very well, regularly, fairly strongly, up to death. I have seen such a case, a heart looking almost like fat after death, and pronounced to be in a state of fatty degeneration, not mere fatty infiltration, yet in the hour of death the pulse, as I remember, about 84. Then I have known cases in which the clinical diagnosis seemed to be myocardial disease, and the pathologist found no changes in the heart. The difficulty of finding changes in the heart in cases regarded as myocarditis would seem to have been experienced by more than one observer. I remember some European authority says that in order to exclude myocarditis one should make microscopic sections of the whole heart and search all those pieces — which, as it seems to me, indicates a great deal of difficulty in finding the lesion. That brings me to the importance of a disorder of the heart which I do not think has yet been mentioned to-night. The effect of the nerves upon the production of myocarditis has been mentioned, but I believe that the heart may be macroscopically and microscopically normal and nevertheless fatally disturbed on account of ganglionic or nervous derangement. This seems to me a very difficult subject to determine about, and I think a great deal more study and investigation will have to be made before we can form definite and invariably reliable opinions with regard to the working state of the myocardium. This last year Dr. Cheadle of St. Mary's, in a course of lectures, spoke about the fatty degeneration of the heart in cirrhosis of the liver, the cases in which he had noticed it being mainly those due to alcohol, the liver sometimes being large and sometimes small. I was much interested in reading this because I had noticed, in several cases of cirrhotic disease with ascites and an alcoholic history, a mitral regurgitant murmur and an enfeebled heart. He says that the combination is rather common, and has a great bearing upon prognosis and upon treatment.

Dr. Sears: The whole subject of failing heart is introduced by Dr. Jackson's paper, which has greatly interested as well as instructed me. Yet I had hoped for still further instruction which might assist in distinguishing between its various forms. Cardiac failure is a convenient term to append to a certificate of death, but it is frowned upon by the Board of Health as too vague; it may, nevertheless, express the limit of our clinical knowledge, and in the absence of an autopsy be quite as accurate as if a more specific diagnosis were attempted, which we must regretfully admit is often beyond our capabilities. It is occasionally possible to get some help from the etiology, for a history of prolonged strain, or of a sudden effort followed by cardiac symptoms and only partial recovery, would suggest simple cardiac dilatation without degenerative changes, but unfortunately in all the conditions of which Dr. Jackson has spoken the same factors are at times operative and can seldom aid in making a distinction.

If the diagnosis between these conditions is difficult, the prognosis is scarcely easier. I have been struck, as Dr. Vickery has hinted, by the marked ability which some of these weakened hearts possess of resisting further strain. I can remember, for instance, a case which, as there was no autopsy, I will call one of cardiac weakness, occurring in an elderly man with marked arteriosclerosis, whose pulse was frequently 30 and never above 36 per minute, who successfully weathered an attack of double pneumonia. Two months

[1] See page 319 of the Journal.
[2] See page 324 of the Journal.

later after a walk of half a block he fell dead upon the sidewalk.

Dr. Jackson also speaks of the enlargement of the heart which followed arteriosclerosis in all cases among those which he analyzed. It is certainly not a necessary result of that condition when present only in the peripheral arteries as one might theoretically expect to find from the increased work thrown upon the heart. Hasenfeld, in an interesting paper, shows that it leads to hypertrophy of the left ventricle only when the splanchnics or the aorta above the diaphragm are markedly affected. Sclerosis of other vessels did not appear to alter the conditions. In the cases of contracted kidney which he examined, all portions of the heart were invariably hypertrophied, but if at the same time the splanchnic vessels were greatly altered, hypertrophy of the left ventricle predominated. Marked changes in the aorta would probably act in the same way.

Dr. Arnold speaks of the importance of recognizing the fact that cardiac murmurs alone mean little. He might also have emphasized the fact that valvular lesions are occasionally present when there are no murmurs which testify to them. He mentioned this particularly in cases of mitral stenosis. Dr. Shattuck may, perhaps, remember a patient which we saw together two years ago, where we both came to the conclusion that mitral stenosis was present although careful examination then and later, with the exception of one occasion when a slight presystolic thrill was noted, failed to detect a murmur. There was, however, some lateral enlargement and a sharp pulmonic second sound. She was then four months pregnant. On the occasion of the first visit the exertion of walking up the few steps leading to my office brought on so severe an attack of dyspnea and cyanosis that I feared she would die before she could be relieved. On his advice, which agreed fully with my opinion, a miscarriage was immediately induced. She visited me a few weeks ago, and her dyspnea was still very marked after slight exercise, but no change was detected in the physical examination.

DR. WITHINGTON: I suppose we all agree with Drs. Arnold and Sears as to the relative unimportance of cardiac murmurs compared with the condition of the myocardium, and yet, while under careful observation of cases, we are able to say that some disease of the myocardium does exist. I for one do not feel able to differentiate fatty cases from cases of fibroid myocarditis, and I should like to have sombody tell me how to do it. I have known cases in which definite myocardial disease was present and no recognition of that fact was made during life. I recall a case — reported some time ago — in which a patient came from the country and was examined by somebody in town, who assured him he had no cardiac disease whatever, no murmurs being present. The patient went away very much cheered, and died in the cars on his way home of myocardial disease.

One of the results of myocardial disease which has interested me a good deal is the somewhat rare one of cardiac rupture. I knew of a case some years ago — I was not the attending physician — which occurred in a man of seventy-one or seventy-two years, of spare habit, a man of perfectly correct habits, who had never used alcohol at all, who was agile and active, who got up one morning with a sense of oppression at the epigastrium, which was made light of at the time, and was afterwards considered to be due to an overloaded stomach. He stayed in bed during the day; about six o'clock in the evening was taken with severe pain and died in about ten minutes. He was found to have a rupture of the left ventricle, which apparently was due to fatty degeneration of the heart muscle. He had never had any symptoms, whatever, and had been in active life. Looking up other cases of this sort I have found an inaugural dissertation by Dr. Abbt, of Erlanger, in which he gathered some odd cases of cardiac rupture, and in 8 no disease of the myocardium was discovered on post-mortem examination. Of course, there is room for doubt as to how careful an examination was made. It does not appear, for instance, that in all these cases the suggestion just made by Dr. Vickery was followed, to examine every atom of the heart muscle. One of Abbt's cases interested me particularly, that of a man who consulted a physician for some cardiac uneasiness and was found to have rather a weak pulse. He was helped home and got better, and lived about two days, at the end of which time he died suddenly, and a rupture was found in the septum between the two ventricles which contained a thrombus.

In some of these cases it was curious to observe that the rupture, as in the case I first spoke of, took place not under violent exertion, but with the patient in bed and perfectly quiet.

The general subject of the condition of the myocardium is one of the very greatest importance, and one I am glad to hear emphasized as it has been tonight. It seems to me probable that the causation of these cases is very largely toxemic. In influenza, diphtheria and pneumonia we know an acute myocarditis is present, undoubtedly of toxic causation, and that the same causation plays a part, directly or indirectly, in the more chronic cases seems probable. Alcohol has been spoken of as one of the great factors. Possibly ptomaine poisoning may play a part in other cases. These toxic agents may either affect the heart muscle directly and primarily, or else secondarily through an intermediate affection of the blood vessels.

DR. F. C. SHATTUCK: There is an embarrassment of riches, Mr. Chairman, and it is very difficult to select any subjects for remark, because I have not any serious criticism on either of the papers which we have heard. Dr. Jackson said that the books did not give enough relative attention to myocarditis. It is perfectly true, but the trouble lies in our lack of knowledge. The accuracy, as it seems to me, is surprising with which we can determine the state of the heart valves considering the conditions under which we work. It seems to me very remarkable how closely in the majority of cases we

can determine the condition of valves by, as Dr. Arnold well said, a careful consideration of all the factors in the case; the murmur, as I said years ago in a paper on this subject, being the smallest part of the evidence on which we convict a valve. When we come to the condition of the heart wall we have not the same data to go upon; we have got to do lots of guesswork. It is very largely a matter of inference. Dr. Withington said he should be glad to have some one tell him how to distinguish between a heart degenerated from fibroid and one degenerated from fatty change. We should all be glad to have a revelation from on high or any other place on that subject. It appears to me absolutely a matter of surmise, and Bramwell puts it very well: "we can say that a heart is weak, but whether due to fibroid or fatty degeneration is sheer guesswork in the vast majority of cases." It is a pity that it should be so, because, of course, as has been already emphasized, it is the myocardium which is the vital thing. The valves play a passive, a purely mechanical part as it were. It is the condition of the myocardium we want to determine, and yet that is so difficult; and here comes in the proverbial uncertainty of prognosis in heart disease. What the condition of the myocardium is, whether dilatation is so predominant over hypertrophy that the heart is nothing but a stretched old rubber bag, whether the degenerative or inflammatory changes have passed the stage of even partial remedy is purely a matter of inference. There is nobody in this room who has not seen cases of heart disease do much better than he supposed they were going to, and has not seen other cases of cardiac disease do less well than he thought they would. It seems to me that one very important factor in prognosis should always be the chance which the patient has had up to that time.

DR. ARNOLD: I am very glad Dr. Sears spoke of the question of cardiac valvular disease without murmurs. I agree with him thoroughly as to the importance of the subject. The condition of the myocardium in the case Dr. Withington spoke of, where there was no valvular disease and no murmurs, brings up another important topic in this connection. It is well to have these points emphasized, though lack of time prevented their due consideration in a paper on the murmurs themselves. It has been shown experimentally that the mitral orifice contracts in systole. Examination of the heart with the x-ray shows that a marked contraction of the heart occurs laterally at the base in normal cases, so that it seems to me that the evidence that some contraction takes place is pretty clear. Furthermore, we find that these murmurs of mitral regurgitation occur in mild attacks of influenza, in measles, and in cases of mild debility so that it would seem that very slight disturbance of the myocardium is enough to disturb the perfect closure of that valve. That is the reason why I have assumed that some narrowing of the mitral orifice really is necessary for the perfect closure of the valve.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 4, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE ETIOLOGY OF YELLOW FEVER.

DRS. REED, CARROLL AND AGRAMONTE, of the U. S. Army, detail in the *Journal of the American Medical Association* for February 16th the results of an interesting series of experiments made in Cuba, to which we have already briefly alluded, for the purpose of determining certain questions relating to the transmission of the infection of yellow fever.

An experimental camp was established in an open field, under good sanitary conditions, about a mile from the town of Quemados. The persons selected for experiment were non-immunes who were each paid a fee for the purpose of the experiment, and the experiments were performed with their full knowledge and consent in each case. Mosquitoes were obtained which had already been in contact with and had bitten persons ill with yellow fever and were allowed to bite these men who were thus selected.

The authors write as follows:

In considering the character of the attacks and the course of the disease in these five cases of experimental yellow fever, it must be borne in mind that these infected individuals were all young men, in good general physical condition and placed amid excellent hygienic surroundings. In our opinion the experiment above described conclusively demonstrates that an attack of yellow fever may be readily induced in the healthy subject by the bite of mosquitoes (*culex fasciatus*) which have been previously contaminated by being fed with the blood of those sick with yellow fever, provided the insects are kept a sufficient length of time after contamination before being applied to the person to be infected.

Our observations do not confirm Finlay's statement that the bite of the mosquito may confer an abortive attack of yellow fever, when applied to the healthy subject two to six days after it has bitten a yellow fever patient. We have always failed to induce an attack, even of the mildest description, when we have used mosquitoes within less than twelve days from the time of contamination, although the insects were constantly kept at summer temperature. We could cite instances

where we have applied mosquitoes at intervals of two, three, four, five, six, nine and eleven days from the time of contamination of the insect with the blood of well-marked cases of yellow fever, early in the disease, without any effect whatever being produced by the bite. Thus in one case no result followed the bite of fourteen mosquitoes which four days previously had been contaminated by biting a case of yellow fever on the first day. Again, seven days later, or eleven days after the contamination, the surviving seven of these insects failed to infect an individual. On the seventeenth day after contamination, however, the bite of four of these mosquitoes — all that remained of the original fourteen — was promptly followed by an attack of yellow fever in the same individual. These insects had been kept, during the whole of this time, at an average temperature of 82° F.

Our observations would seem to indicate that after the parasite has been taken into the mosquito's stomach, a certain number of days must elapse before the insect is capable of reconveying it to man. This period doubtless represents the time required for the parasite to pass from the insect's stomach to the salivary glands, and would appear to be about twelve days in summer weather, and most probably about eighteen or more days during the cooler winter months. It follows, also, that our observations do not confirm Finlay's opinion that the bite of the contaminated mosquito may confer immunity against a subsequent attack of yellow fever. In our experience, an individual may be bitten on three or more occasions by contaminated mosquitoes without manifesting any symptoms of disturbance to health, and yet promptly sicken with yellow fever within a few days after being bitten by an insect capable of conveying the infection.

Another series of experiments was devoted to the task of determining whether clothing and bedding that have been contaminated by contact with yellow fever patients and their discharges can convey the disease. Hitherto great importance has been accorded by boards of health to the question of disinfecting all the clothing and bedding of persons coming from yellow fever districts. The mere fact that such persons had resided, even for a day, in a yellow fever district has been sufficient cause to subject their baggage to rigid disinfection by sanitary authorities. For purpose of these experiments a building was erected having a capacity of 2,800 cubic feet. Clothing and bedding thoroughly infected with yellow fever excreta were placed in this room after having been shaken out in the room to disseminate the specific agent of yellow fever. Various soiled articles were hung about the room and placed about the beds. Seven non-immunes slept in this room each night for a period of twenty days, and in some instances they slept with heads upon towels thoroughly soaked with infected blood drawn from patients during an attack of yellow fever. This attempt to infect by means of fomites proved an entire failure.

Other experiments were tried to determine the answer to the question, "How does a house become infected with yellow fever?" In this instance, a room was divided by a mosquito-proof screen, but so arranged that the air could circulate freely from one side to the other, windows being placed on opposite sides of the apartment. On one side of this screen fifteen mosquitoes were set free, which had been previously contaminated by biting yellow fever patients at different intervals before the experiment. A non-immune entered the room, remained thirty minutes and was bitten by several insects. He entered the room again in the afternoon and again the next day, and was bitten each time. On the fourth day this man was taken ill with yellow fever. Another man entered the same apartment, but was bitten by only one insect, and he entered the next day with the same result, but this man was not taken ill. It was quite possible that he was bitten by insects which had bitten yellow fever patients less than thirteen days before. During these experiments, two other non-immunes entered the same apartment, but on the other side of the screen, where there were no mosquitoes; and slept in this apartment eighteen nights with the result of remaining in perfect health.

As a result of this series of experiments the authors formulated the following conclusions:

(1) The mosquito (*culex fasciatus*) serves as the intermediate host for the parasite of yellow fever.

(2) Yellow fever is transmitted to the non-immune individual by means of the bite of the mosquito that has previously fed on the blood of those sick with this disease.

(3) An interval of about twelve days or more after the contamination appears to be necessary before the mosquito is capable of conveying the infection.

(4) The bite of the mosquito at an earlier period after contamination does not appear to confer any immunity against a subsequent attack.

(5) Yellow fever can also be experimentally produced by the subcutaneous injection of blood taken from the general circulation during the first and second days of this disease.

(6) An attack of yellow fever, produced by the bite of a mosquito, confers immunity against the subsequent injection of blood of an individual suffering from the non-experimental form of this disease.

(7) The period of incubation in thirteen cases of experimental yellow fever has varied from forty-one hours to five days and seventeen hours.

(8) Yellow fever is not conveyed by fomites, and hence disinfection of articles of clothing, bedding or merchandise, supposedly contaminated by contact with those sick with this disease, is unnecessary.

(9) A house may be said to be infected with

yellow fever only when there are present within its walls contaminated mosquitoes capable of conveying the parasite of this disease.

(10) The spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitoes and the protection of the sick against the bite of these insects.

(11) While the mode of propagation of yellow fever has now been definitely determined, the specific cause of this disease remains to be discovered.

THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS.

It is significant of the progress in the differentiation of the medical sciences that the time has come for the formation of a new national society, devoted to pathology and bacteriology. In the preliminary announcement the object of this new association is simply stated to be the advancement of the knowledge of disease, without further statement as to its scope of activity. The promoters of the new society have no doubt considered carefully the arguments now so frequently heard for and against the multiplication of medical associations, and have, wisely we think, in this instance, decided to add another to the constantly growing list. The need of a new society must be determined essentially by the enthusiasm of its members, and their capacity for producing work of merit. If new societies, by limiting themselves to certain fields, can encourage men who have already gained a place for themselves, and especially those just entering upon their professional lives, to do really good research work, we have no right to call them unnecessary or superfluous. Time alone can show how far any given society will accomplish this object; it depends, naturally, upon many conditions, but we are confident, if the topics discussed are fundamentally important, that the gathering of men interested in the same general subject into a society is the best possible way to forward the progress of medicine at large. Men who take part in such meetings demand an intelligently sympathetic audience. Nothing is more harassing to a reader than the consciousness of lack of interest on the part of his auditors, and nothing is more irksome to an audience than a paper in which it has no interest. For all concerned, then, whether we relish the prospect or not, the special society composed of men interested in the same subjects is an institution which has come to stay. The more special the topic the more limited will be the membership; but it must always be remembered that the ultimate product of these deliberations, so far as they are valuable, must finally become common property, and so justify the seeming exclusiveness which gave them birth. We have no doubt the new society of Pathologists and Bacteriologists, standing as it does in intimate relation with every branch of so-called practical medicine, will at once justify its separate existence.

MEDICAL NOTES.

Plague Situation at Cape Town. — Recent reports from South Africa regarding plague are somewhat disquieting. A number of natives and a few Europeans are being attacked by the disease. There is 1 case in the Queen's regiment at Simons Town, 1 in the First Royal Irish, at the Greenpoint camp, and 1 in the Royal Garrison Artillery, at Castle, one of the suburbs of Cape Town. Some of the Malays have offered opposition to the removal of plague patients, and also of the bodies of those who have died of the disease. The government has informed these people that if this obstruction continues, the Malay community will be isolated outside the city. The latest report gives 17 new cases. Four are Europeans. The total number of cases thus far is 287 and the deaths 99. One of the doctors attending the plague patients has contracted the disease.

Hospital at the Pan-American Exposition. —The management of the coming Pan-American Exposition at Buffalo proposes to maintain on the grounds a fully equipped hospital during the progress of the Exposition. It has already been used to a considerable extent as shown by the fact that up to the first of March, five hundred and four cases have been treated on the grounds, only one of which proved fatal. These include all forms of sickness and accidents to workmen employed upon the construction work. The hospital is under the directorship of Dr. Roswell Park.

Death Rate from Plague in Bengal. — A despatch from Calcutta announces that last week 8,000 persons died of plague in Bengal alone, including Calcutta. Towns are being deserted, but there is said to be no panic.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 3, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 88, scarlatina 27, measles 103, typhoid fever 4, smallpox 1.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending March 30th, was 244, against 316 the corresponding week last year, showing a decrease of 72 deaths, and making the death rate

for the week 22.7. The deaths from consumption were 31, pneumonia 43, whooping cough 1, heart disease 30, bronchitis 8 and marasmus 1. There were 10 deaths from violent causes. The number of children who died under one year was 39, the number under five years 66. The number of persons who died over sixty years of age was 52. The deaths in public institutions were 84. There were 5 deaths from influenza during the week, all complicated with other diseases.

OPPOSITION TO MAINE EYE AND EAR INFIRMARY. — By a large majority the Maine House of Representatives has voted not to appropriate $5,000 annually, which has been asked for the support of the Maine Eye and Ear Infirmary, located at Portland.

NEW YORK.

INCREASE OF SCARLET FEVER AND DIPHTHERIA. — There has of late been a considerable increase in both scarlet fever and diphtheria. In the week ending March 16th there were 608 cases of the former reported, an increase of 46 over the previous week, and 324 cases of the latter, an increase of 63. Since January 1st 4,959 cases of scarlet fever have been reported in the city, and a noteworthy fact in connection with the present epidemic of the disease is the unusually large proportion of adults attacked. It is however of a comparatively mild type. Thus, while there were 29 deaths from scarlet fever in the week ending March 16th, against 15 for the corresponding week of last year, the cases reported during the week in 1901 were nearly three times as large as in 1900.

OSTEOPATHY: ASEPTIC VACCINATION. — At a meeting of the Medical Society of the County of New York, held March 25th, a resolution was adopted protesting, in view of the recent introduction of bills legalizing the practice of osteopathy, against the enactment of any measure giving the right to treat disease unless a compliance with the medical laws of the state is a prerequisite. The paper of the evening was by Dr. W. K. Kubin, on "The Importance of Aseptic Vaccination." In the discussion which followed it was agreed that vaccination shields were a source of more injury than benefit, and Dr. George H. Fox suggested that the scab should be removed artificially by the physician.

ENTIRE STOMACH REMOVED. — On March 29th Dr. George R. Fowler, at the German Hospital in Williamsburgh, Borough of Brooklyn, removed the entire stomach of a patient, sixty years of age, for cancer. Two malignant growths were found in the organ, one situated near the cardiac orifice and one near the pylorus.

THE ETIOLOGY OF CANCER. — Dr. H. R. Gaylord, who has been in charge of the New York State Cancer Laboratory, at Buffalo, since its establishment three years ago, has just made public a report of the most recent investigations conducted at the institution, and announces with positiveness that he has identified the parasite claimed to be the essential organism of the disease.

APPROPRIATION FOR NEW SMALLPOX PAVILION. — The Board of Estimate and Apportionment has recently made an appropriation of $10,000 for a new smallpox pavilion on North Brother Island to accommodate 50 patients.

Miscellany.

EXTENSION OF MEMBERSHIP OF BOSTON MEDICAL LIBRARY.

THE following circular letter has been sent to certain physicians in and about Boston, with the purpose of exciting a greater interest in the library and its objects than at present exists:

Twenty-five years ago the tireless energy of a small group of Boston doctors who had the foresight to realize that a good medical library was essential to medical growth, set in motion the enterprise which has just given birth to the new and beautiful library building on the Fenway. As a warrant to high standards of medical education, and as a means to bind together men by whom knowledge is held in respect, this movement is second in importance only to the founding of the medical school itself, and because it has been felt to be of this significance, it has secured the generous support in time and money, even, of many physicians who rarely have the opportunity to consult the books upon the library shelves.

At the last meeting of the library a new departure, alluded to in our issue of last week, was decided on, for the success of which your co-operation is required. The library was never intended to be an institution of Boston only, but an institution of Massachusetts or of New England. We wish a wider sympathy and support from physicians of towns and cities outside of Suffolk County, for they too, for their own sake and the credit of the profession, and for the sake of the coming generations are bound to have the success of this movement at heart. The new building, erected almost wholly through the devotion of members of the profession, offers you a convenient and pleasant place for friendly meeting; the information which will some day be indispensable to you is here ready to your hand; those of your sons who follow in your steps will find here the inspiration essential to their success.

Correspondence.

WHEY CREAM MODIFICATIONS IN INFANT FEEDING.

PHILADELPHIA, PA., March 19, 1901.

MR. EDITOR: In the report, in your issue of March 7th, of the discussion following the paper of Drs. White and Ladd on "Whey Cream Modifications in Infant Feeding," the impression is given that the use of whey as a substitute for, or modifier of, cows' milk in the artificial feeding of infants, was regarded as a new device by

some of the debaters. Any one, however, at all familiar with the history of infant feeding, must know that whey has been used as a substitute for milk in infants with feeble digestion for fully forty or fifty years; also, that the employment of whey as a modifier of cow's milk, so as to reduce the casein of the latter, and, at the same time, maintain the nutritive value of the mixture by the use of the proteids of the whey, dates, likewise, from an early period. Mixtures of whey and cream are recommended in the first edition of Eustace Smith's "Wasting Diseases of Children" (1868), while the earliest mention I can find of Dr. Frankland's method of treating milk for infants is in Routh's "Infant Feeding," published in 1860. This method consisted in removing the cream from a given quantity of milk, separating the casein from the remaining skim milk by the action of rennet, scalding this whey and adding milk sugar, mixing this with an equal or twice its quantity of whole milk, and finally adding the removed cream. A modification of this method has long been in use throughout Great Britain under the name of "Humanized Milk." Whey and cream mixtures have also for many years been a favorite resource of Louis Starr in difficult cases. A process similar to that of Backhaus' (described by Dr. Wentworth in the discussion of Drs. White and Ladd's paper) is given by Henry Ashby in the *Edinburg Medical Journal* (N. S. 5, p. 389, 1899). The following formulæ are recommended by this author for infants who have difficulty in digesting the curd of cow's milk:

I.

Milk, 10 ounces,	Proteids,	1.75.
Sterilized Whey, 20 ounces,	Fat,	2.50.
Sugar of Milk, 1-2 ounce,	Sugar,	6.00.
	Salts,	.60.

II.

Top Milk, or 8% Cream, 10 ounces,	Proteids,	1.75.
Sterilized Whey, 20 ounces,	Fat,	4.00.
Sugar of Milk, 1-2 ounce,	Sugar,	6.00.
	Salts,	.60.

The high proportion of fat in these mixtures is due to vigorous agitation of the curd before straining, whereby, according to Ashby, the whey is made to take up more fat (1.75% to 2.00%) than is accomplished by the ordinary method of preparation. It is thus quite evident that the idea of utilizing the whey proteids in reducing the casein of cow's milk is not of recent date. The older pediatrists, of course, did not do this in any accurate or scientific manner. This was reserved for Backhaus, to be still further elaborated by Westcott, Rotch, White and Ladd. The objection to the method, as far as the home modification of milk is concerned, is that it would complicate still more an already somewhat complicated process, when our aim should be in the direction of simplicity. Moreover, it does not seem to me to be necessary. I have not found that healthy infants usually have difficulty in digesting the casein of properly modified cow's milk, nor does there seem to be any reason why we should aim, as Dr. Rotch suggests, to give 2% of total proteids by the fourth or fifth month, as this process is said to enable us to do, when breast-fed infants are well nourished with from 1.25% to 1.50% at the same age. In feeble and dyspeptic infants, however, who cannot digest the casein of cow's milk, sometimes even when given in the weakest dilutions, these whey cream modifications will undoubtedly be of the utmost value; but outside of the laboratories I fear their general use will be postponed until a ready method of calculation at the bedside can be obtained.

Very truly yours,

D. J. MILTON MILLER.

THE USE OF ANTITOXIN.

MR. EDITOR. — The blast against the use of antitoxin which was published in the Boston *Evening Record* of Friday, March 29th, by Rev. D. S. Coles, A.M., M.D., etc., etc., has the familiar stamp of a very small number of physicians who, in America, have condemned antitoxin from the outset. One would suppose from the tone of this article that patients and physicians were compelled to use antitoxin. We are not aware, however, that such is the case in any country.

In this article the following statement runs: "I predict that in a few *short* years this horse serum fad will be relegated to the same medical dump, etc." This same writer used precisely the same language in one of his publications in 1896. Now, what are the facts? In the last report of the State Board of Health the number of packages of antitoxin issued has been as follows: 1895, 1,724 bottles; 1896, 3,219 bottles; 1897, 4,668 bottles; 1898, 12,491 bottles; 1899, 31,997 bottles. That is to say, beginning with 0 in 1894 the board has issued nearly 55,000 packages, not in a decreasing ratio, but in a rapidly increasing one from year to year, a fact which does not look much like going to the "dump heap."

It would be interesting, though perhaps impossible, to ascertain the actual fatality of diphtheria in the hands of physicians who still reject the use of antitoxin, of which fortunately there are very few in Massachusetts. There is, however, on record the experience of at least one suburban town. In this town there were in all 124 deaths in 1900. Out of this number 5 were deaths from diphtheria, and of these 5, 3 occurred in the practice of the only physician who persisted in his opposition to the use of antitoxin. It is also quite remarkable that these 3 deaths were all of persons who were over ten years old — an age when deaths from diphtheria are quite uncommon.

PHYSICIAN.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 23, 1901.

Deaths reported 2,619; under five years of age 803; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 582, acute

lung diseases 506, consumption 299, diphtheria and croup 95, diarrheal diseases 60, scarlet fever 49, typhoid fever 21, whooping cough 14, cerebro-spinal meningitis 8, measles 6, erysipelas 12, influenza 12.

From whooping cough, New York, 4, Baltimore, 1, Pittsburg, 2, Providence, 1, Lowell, 1, Haverhill, 1, Malden, 2. From cerebro-spinal meningitis, New York, 4, Baltimore, 1, Worcester, New Bedford and Medford, 1 each. From scarlet fever, New York, 40, Pittsburg, 1, Boston, 4, Brockton, 2, Medford and Revere 1 each. From typhoid fever, New York, 5, Baltimore, 1, Pittsburg, 12, Providence, 1, Boston, 2. From erysipelas, New York, 7, Baltimore, 2, Boston, 3. Measles, New York, 4, Pittsburg, 2. From smallpox, New York 6.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending March 9th, the death rate was 19.5. Deaths reported, 4,419; acute diseases of the respiratory organs (London), 463, whooping cough 91, diphtheria 74, measles 118, diarrheal diseases, 39, fever 22, scarlet fever 32.

The death rates ranged from 8.9, in Croydon to 34.2, in Plymouth, Birkenhead, 16.2, Birmingham, 21.0, Bolton, 17.2, Bradford. 16.3, Brighton, 17.5, Bristol, 21.9, Burnley, 16.9, Cardiff, 20.0, Derby, 15.2, Gateshead, 19.0, Halifax, 23.4, Hull, 21.2, Leeds, 18.7, Leicester, 18.3, Liverpool, 26.3, London, 19.3, Manchester, 23.6, Newcastle-on-Tyne, 17.6, Norwich, 16.1 Oldham, 18.7, Portsmouth, 17.5, Preston, 18.2, Salford, 23.3, Sheffield, 19.7, Swansea, 20.9, West Ham, 11.6, Wolverhampton, 13.3.

METEOROLOGICAL RECORD.

SOCIETY NOTICE.

CHANGE OF DATE OF ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY. — Owing to conflict with the date of meeting of the American Climatological Society the annual meeting will be held at the New York Academy of Medicine in New York City on May 23, 24 and 25, 1901, instead of at the time previously announced.

RECENT DEATHS.

DR. JOHN HENRY HOBART BURGE, a physician who had been in practice in Brooklyn, New York, for fifty years, died on March 24th, in the seventy-eighth year of his age. He was born at Wickford, R. I., August 12, 1823, and studied at the Harvard Medical School and the Medical Department of the University of the City of New York. At the time of his death he was consulting surgeon to the Long Island College Hospital, St. John's Hospital and the Sheltering Arms Nursery.

DR. MYRON H. PARKHILL, Coroner of Steuben County, died at his home in Howard, N. Y., on March 26th of pneumonia after a brief illness, at the age of thirty-five.

GEORGE HAYWARD, M.D., M.M.S.S., died in Boston, March 30, 1901, aged eighty-one years.

BOOKS AND PAMPHLETS RECEIVED.

On the Treatment of Metacarpal Fracture. By Carl Beck, M.D., New York. Illustrated. Reprint. 1900.

On a Grave Possible Error in Skiagraphy. By Carl Beck, M.D., New York. Illustrated. Reprint. 1900.

Registration of Tuberculosis. Published for Gratuitous Distribution by the Pennsylvania Society for the Prevention of Tuberculosis. Reprint. 1901.

The General Practitioner. By James Tyson, M.D., Philadelphia, Professor of Medicine in the University of Pennsylvania, etc. Reprint. 1898.

How to Avoid Contracting Tuberculosis (Consumption). Published for Gratuitous Distribution by the Pennsylvania Society for the Prevention of Tuberculosis. Reprint. 1901.

The Operation for Hypospadias, with the Demonstration of Three Cases, Successfully Treated by the Forward Dislocation of the Urethra. By Carl Beck, M.D., New York. Illustrated. Reprint. 1900.

Predisposing Causes of Tuberculosis and How to Avoid or Overcome Them. Published for Gratuitous Distribution by the Pennsylvania Society for the Prevention of Tuberculosis. Reprint.

How Persons Suffering from Tuberculosis can Avoid Giving the Disease to Others. Published for Gratuitous Distribution by the Pennsylvania Society for the Prevention of Tuberculosis. Reprint. 1901.

A Scientific Basis for Medicine. Life and Its Association with Matter: Matter not Vital but Absolutely Chemical. By E. C. Hebbard, M.D., Boston, Mass.; Member Massachusetts Medical Society. Reprint. 1901.

How Storekeepers and Manufacturers Can Help to Prevent the Spread of Tuberculosis. Published for Gratuitous Distribution by the Pennsylvania Society for the Prevention of Tuberculosis. Reprint.

A Treatise on Appendicitis. By George Ryerson Fowler, M.D., Professor of Surgery in the New York Polyclinic, etc. Second edition, revised and enlarged. Philadelphia and London: J. B. Lippincott Company. 1900.

Manual of the Diseases of Children. By John Madison Taylor, A.M., M.D., and William H. Wells, M.D. Second edition, thoroughly revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1901.

The History of Medicine in the United States. A Collection of Facts and Documents relating to the History of Medical Science in this Country, from the earliest English colonization to the year 1800. With a supplemental chapter on The Discovery of Anesthesia. By Francis Randolph Packard, M.D. Illustrated. Philadelphia and London: J. B. Lippincott Co. 1901.

The Position of Ophthalmology in the Curriculum of the Modern Medical School, with some Suggestions as to the method of teaching it. By Swan M. Burnett, M.D., Ph.D., Professor of Opthalmology in the Medical School of Georgetown University; Director of the Eye and Ear Clinic, Central Dispensary and Emergency Hospital, etc., Washington, D. C. Reprint. 1901.

Sonderabdruck aus dem Archiv für Laryngologie. Ein Wort zu Gunsten der Diagnose mit blossem Auge und der Entfernung des ganzen Organs mitsammt dem Nachbargebiete möglicher lymphatischer Infection bei Kehlkopfkrebs. By Prof. Dr. John N. Mackenzie, Prof. der Laryngologie u. Rhinologie an der Aerzte-Schule der Johns Hopkins Universität und Laryngologie am Johns Hopkins Hospital. Reprint. 1901.

The American Yearbook of Medicine and Surgery: Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs and Textbooks of the Leading American and Foreign Authors and Investigators. Collected and arranged with critical comment by various authors under the general charge of George M. Gould, M.D. In two volumes. Philadelphia and London: W. B. Saunders & Co. 1901.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Assisted by H. R. M. Landis, M.D. Volume I., March, 1901. Surgery of the Head, Neck and Chest; Infectious Diseases, including Acute Rheumatism, Croupous Pneumonia and Influenza. Diseases of Children; Pathology, Laryngology and Rhinology; Otology. Lea Brothers & Co. Philadelphia and New York. 1901.

A REVIEW OF THE LITERATURE OF THE THERAPEUTIC USE OF THE X-RAYS.

BY HARVEY P. TOWLE, M.D., BOSTON,

Assistant to the Physicians for Diseases of the Skin, Boston City Hospital; Assistant, Carney Hospital, Skin Out-Patient Department.

As all will remember it is now six years since Röntgen startled the world by the announcement of his discovery of a new form of energy, which, because of its unknown character, he called the x-rays. These rays had the power of penetrating the human body, and were recognized at once as a most efficient aid to diagnosis. The use of them speedily became general. It was not long, however, before it was recognized that care must be exercised in the use or harm might result. The medical press began to receive report after report of injuries attributed to the x-rays. These injuries it was noted were all of the same type, varying only in degree. As the reports multiplied it gradually became known that the x-rays, or something accompanying them, had a distinct action upon the skin. Freund was the first to recognize this action and to suggest the use of the rays for the treatment of diseases of the skin. It was in connection with their use in dermatology that I was led to investigate the reports of the cases of skin disease, in the treatment of which the x-rays had been used as a therapeutic measure, in order to learn, as far as was possible through the literature, the theory of their action; the changes induced by them in the skin; in which diseases they had been used; the value of the treatment and the method of using them. The following is an attempt to show what has been found, without going into unnecessary detail or multiplying examples, giving, merely, an illustrative case under each topic and a very brief statement of the facts.

As has been already hinted, a vigorous discussion arose, which is still in progress as to the real nature of the rays, and as to whether the results obtained arose from the action of the rays themselves, or of something accompanying them. One early opinion was that the effects were due to the generation of ozone upon the skin.[1] There was another theory that the rays were chemical, like the ultraviolet.[2] In this connection it is interesting to note that Dr. Bowles, who has been investigating the effects of sunlight on the human body, and especially of the reflected rays from snow, concludes [2] that he cannot avoid the feeling that the x-rays will be shown to be modifications, only, of ordinary light. It was also asserted by another observer that the spot treated was bombarded by particles from the platinum electrode. Eder and Freund [3] advanced the theory that there is a disturbance of the electrical equilibrium of each molecule causing it to yield up its electricity. Still another theory was that the x-ray was a combination of different rays each doing its own work. Jutassy[4], among others, supports the theory that the changes are due to the x-rays themselves. Balthazard, as reported by Jutassy,[4] thinks that the effects are produced by the electric zone which arises about the Röntgen lamp. In an article published May, 1900, Schiff [5] quotes Freund's opinion as being that there is ground for assuming that the therapeutical effects obtained are due to electric waves, arising, in the case of the electric discharges, in the vacuum tubes under the same potential of discharge as the x-rays. Hall-Edwards [6] states that Tesla has shown that the placing of a sheet of aluminum between the tube in action and the skin has the effect of stopping all danger of burns. "Now, as aluminum is exceedingly transparent to the x-rays and allows them to pass through with great freedom, it is safe to say that the x-rays themselves play little or no part in the process." He is inclined to think that the effects produced are entirely electrical in their origin. (Further observations having a bearing on this point will be given in the description of the histological changes.)

In the earlier days of the use of the rays, before their management was as well understood as at present, "accidents," *i.e.*: cases of dermatitis, were not uncommon. Every author now emphasizes the fact that great care must be exercised in the use of the x-rays and that no one without experience in the use of the rays should attempt to employ them. As it was these so-called accidents which first called attention to the possibility of using the x-rays therapeutically, and as they present certain features which throw light on the peculiar effects of the x-rays, and which help to explain why they are used as a curative agent, it will be profitable to consider rapidly this x-ray dermatitis.

It has been noticed that a certain sequence of events always follows on the continued use of the rays when the use is pushed to the point of visible reaction. Albers-Schönberg describes the process as follows:[7] "First, a slight yellow coloring appears growing to a diffuse redness which later becomes a darker red. Light itching and prickling are experienced by many at this stage. Next there is a general feeling of warmth. With increasing redness comes edema of the skin. On continued exposure the skin becomes even darker. Small vesicles appear which become excoriated and the process spreads all over the exposed area. The process resembles that in burns. This may go on until a gangrenous ulceration results which has absolutely no tendency to heal. Over the excoriated parts healing is extraordinarily slow and it is months before a normal skin is reproduced."

I wish to give a few cases of x-ray dermatitis to illustrate the points given above, particularly the slowness of recovery. Drury [8] reports a case which was exposed for one hour, tube distant one to two inches. Three hours later nausea. Later, case exposed one and one-half hours. Redness next day which increased (without further exposure) until, on the fourth day, vesicles appeared which ruptured, leaving excoriations with a profuse discharge. Healing was very slow. Sixteen weeks after exposure the ulcer was still open and

it became necessary to etherize and curette. Crocker[9] reported the case of a boy who had one exposure of one hour. Tube distance, 5 inches. Next day, skin red; sixth day, skin stiff; ninth and tenth days, vesicles; eleventh day, vesicles began to rupture, leaving an excoriated surface which healed very slowly. The ulcer was not entirely healed three months later. Bannister[10] reports the case of an army officer who was exposed for a radeograph to locate a bullet. As attempts to get a good picture failed the patient was given eleven sittings with a total exposure of over fifteen hours. On the first day of the last series the skin began to show signs of inflammation which extended during the trial. The epidermis was shed leaving exposed a red hyperesthetic area one-half the size of a man's hand. There was also a profuse outpouring of serum. Large blisters formed rapidly such as are seen in scalds. The man had been in bed for a month at the time of the report and the wound was still so tender that he could not endure a dressing upon it. Apostoli[11] reports a case where the wound was open for over one year.

These cases will serve to show the caution that care must be exercised in using the rays no idle one. Mies,[12] Sehrwald,[13] Fuchs,[14] Lee,[15] King,[16] Gilchrist,[17] and Bronson,[18] among others, have reported cases of x-ray dermatitis in which serious injury with a very slow recovery was a marked feature. These cases recovered and I have not yet come upon a case in which death has resulted directly from the x-rays, but reprinted in a recent number of the *Boston Medical and Surgical Journal* was a case, taken from the *Lancet*, of an old lady of sixty-eight who was exposed by a layman several times. A large slough developed and several months later she died, being unable to stand the drain in her enfeebled condition.

It is only fair to state at this point that accidents are now rare, the knowledge that they may occur enabling the present day operator to guard against them. All operators now insist that a patient's susceptibility to the rays must be determined before further treatment is carried on, a measure taken to prevent such injuries as those mentioned above.

Before leaving these cases I wish to call attention to the variability of the time of the appearance of the first symptoms, the similarity of the lesions to those produced by burns and the marked tendency to a slow recovery. These points are still further brought out in a series of 69 cases reported by Dr. Scott,[19] especially the varying susceptibility to the rays as shown by the time of the appearance of the first symptoms and the varied lengths of exposure which caused symptoms. In this series the average is three and one-half hours — the longest was twenty-four hours, the shortest twelve minutes. The average distance of the tube from the part exposed was in 25 cases a little over 6 inches — the greatest 18 inches with 19 exposures; the shortest ½ inch with one exposure of half an hour. The shortest time noted for the first appearance of symptoms was during exposure, the longest four weeks(?), the average in 31 cases being one and two-sevenths days. These figures are taken from cases collected in 1897. Today, as will be shown later, in speaking of the method of using, the length of exposure and the tube distance have been very much modified.

In addition to this review of the macroscopical changes a closer study of the microscopical changes is necessary in order to understand on exactly what grounds the therapeutical use of the x-rays is based. Kaposi[8] had explained on clinical grounds the effects produced. He said, there is caused first a fleeting hyperemia then a paresis of the deeper vessels of the skin, which change then extends to the superficial vessels and induces a true hyperemia. It is interesting here to compare this opinion given early with one given lately by Schiff and Freund[20] that according to present knowledge and experiments the greater part of the action is upon the vessels of the skin. Since Kaposi's explanation was made many microscopical examinations have been made. In a recent article by Allbers-Schönberg and Hahn[7] it is said that Oudin, Barthélemy and Darier found a thickening of the epidermis, increase of keratohyalin and atrophy and disappearance of the hair follicles and glands. Kibbe[21] in a mild case of dermatitis found changes in the outer cells of the rete especially in the nuclei, increase in the keratohyalin. The corium showed the ordinary changes of a mild dermatitis, capillary dilatation with round-celled infiltration most marked about the hair follicles. Gassman[7] in an ulcer caused by the x-rays found that "repair was by granulation tissue not different from that in ordinary ulcers; the vessels of the cutis and subcutis showed characteristic changes — growth and vacuolising degeneration of the intima." According to Jutassy[4] most authors are agreed that the histological changes are the same as those in ordinary inflammation. He also found the hair papillæ atrophied and the hair follicles filled with a connective tissue rich in cells. Unna was the first to discover special changes in the collagen. He also found that the lymph spaces had nearly disappeared and that the elastic fibres could not be demonstrated.

It is interesting at this point to compare the changes caused by the use of the x-ray with changes caused by the direct spark as given by Freund[20] as the result of some experiments made by him. He says that the direct spark, whether as a direct discharge from the pole or as an "affluvium," will cause in animals a falling of the hair; that the direct spark will kill bacteria; that the effect can be produced through thin sheets of wood, paper, aluminum and the human skin; that the physiological effect of the negative spark is greater than that of the positive; that the x-rays, according to these researches, have themselves no physiological meaning; that the pathological changes in the skin, caused by the direct spark, consist of hemorrhages into the cutis, in inflammation and in vacuolization of the vessels.

As the x-rays seem to have an especial value in the treatment of certain diseases due to bacteria,

certain investigators made a study of their bactericidal powers. The only positive result which I have seen was that obtained by Rieder.[27] He used different culture media, such as agar, gelatine and serum, spread on glass plates. Over these was placed a sheet of lead in which was a circular aperture. The whole was so arranged that a portion of the culture was freely exposed to the x-rays through the aperture, the rest being protected by the lead. Ordinary light was excluded by pasting black paper over the hole. Cultures of cholera bacilli, anthrax, diphtheria and bacterium coli were exposed from one to three hours to the x-rays from a very powerful machine. The vacuum tube was distant 12 inches. Under the protecting lead the bacteria developed freely; under the aperture no colonies or only a few developed. The x-rays were also effective in stopping the growth of colonies and in this respect were more effective than sunlight. There was no change induced in the gelatine as was shown by the fact that bacteria afterward grew upon it. Wolfenden and Ross,[22] Lyon,[23] Delepine,[24] Sabrazes and Rivière,[25] and Wolff,[26] all made similar experiments. Various cultures of anthrax, bacillus prodigiosus, diphtheria, cholera vibrio and typhoid bacilli were exposed in test tubes to the x-rays. The results were all negative, growth not being interfered with. The weight of the evidence, therefore, would seem to be against the x-rays having any direct bactericidal power.

We have now seen upon what grounds the theory arose that the x-rays might be of therapeutic service in diseases of the skin. This theory was based, not upon a bactericidal power of the x-rays but upon the changes induced in the tissues, especially in the vessels and hair follicles. Freund was the pioneer in the application of the rays to therapeutic uses. His first case was one of nevus Pigmentosus Piliferosus of the back. This being his first case he had not then perfected the method he now uses, so that, in consequence of too long and too intense exposure a dermatitis developed. Notwithstanding this, he considered the results obtained so encouraging that he was led to institute further experiments, both alone and with Schiff, in the removal of hair and in other diseases, notably lupus, until now they have published more cases than any other experimenters. Their reports are especially instructive because they note the strength of current used, the tube distance, the length and number of exposures and the results, with the time elapsed since last treatment, necessary details which many omit from their reports. In June, 1898,[29] they published a series of cases of the removal of hair by means of the x-rays. Similar cases have been reported by others — Behring,[30] Daniel,[31] Wood,[32] Kolle,[33] Gocht.[35] In addition, the falling of the hair has been incidentally noticed by observers who were using the rays for another purpose. In most of these cases and in Schiff and Freund's earlier ones the hair showed signs of returning. Kaposi predicted that in such cases, as soon as the paresis of the vessels had worn off, the tissues would regain their tone and the hair would return. As has been shown in the cases of dermatitis given, the process of repair is a very slow one so that cases now apparently successful may later on show themselves unsuccessful. Freund and Schiff have recognized this fact and have accordingly instituted a method which they think renders the effects permanent. They say in an article, published on June 28, 1898,[34] that it is probable that the hair bulbs and papillæ never will regain their functions because of the changes caused in them by the inflammation. So, by short sittings at the time the return of the hair may be expected, they hope to so upset, and to keep upset, the nutritive condition that the functions will be destroyed either by mechanical alteration or by a paresis of the vessels. They consider that they are borne out in this hope by the fact that the only return was in a case in which these supplementary sittings were omitted. Their cases were, however, reported within a few weeks after the cessation of treatment. In a supplementary report it was stated that six weeks after the first report 1 case was beginning to show a return. This would seem to show that the fact of no return in six or eight weeks is not conclusive. Since then, however, they have reported cases in which there had been no return in two years. One case which has come under my own observation seems to cast some doubt upon the permanency of the effect produced even by repeated series of exposures. The man operated an x-ray machine for a large institution and in the course of his work suffered many and repeated exposures. A very severe dermatitis of the hands resulted but he did not give up his work permanently until he was forced to enter a hospital as a patient. In addition to the dermatitis of the hands, he had lost most of the hair of the face. He did not use the x-ray machine again for several months. Toward the end of this period it was noticed that the hair was returning again. Upon resuming his work the hair fell out again, but when he once more gave up his work the hair returned. This process has been repeated several times. Upon exposure the hair would fall, upon the cessation of work the hair would return slowly after some time. This would seem to indicate that even after the severest injury and when to all appearances the loss of hair is permanent a long time must elapse before the apparent result is accepted as a permanent result.

One case will serve to show the method used by Schiff and Freund in removing hair. A woman applied for the removal of hair on the upper lip and chin. She was given seventeen sittings of ten minutes each from January 4th to 31st: Tube distant, 15 to 20 centimetres; volts, 10 to 11½; amperes, 1½ to 2; intensity medium, 30 centimetres. January 29th: Most of the hair snow white; skin with a dark pigmentation. January 30th: Hair falling. February 3d: Skin smooth, bald; no trace of brown color or erythema. March 20th: About twenty hairs returned. March 20th and 21st: Two sittings of ten minutes each. March

23d: Hair white; fell spontaneously. April 23d: About five hairs to be seen on the chin. April 23d and 24th: Two sittings. April 25th: Hair fell out; no return at the end of May.

The chief therapeutic use of the x-rays, however, has been in the treatment of lupus vulgaris. Freund and Schiff,[3] [34] Kummell,[36] Gocht, Albers-Schönberg,[7] Jutassy,[4] Hall-Edwards,[6] Jones,[37] Himmel[38] and several others have reported cases treated by the x-rays. Schiff and Freund report 2 cases in May, 1898. In the first case treatment was given from January 8th to February 18th. Nineteen sittings of twenty to twenty-five minutes each. March 6th it was noted that there was complete healing over. Smooth white scar. Isolated nodules in surroundings. The second case was treated from December 30, 1897, to April 4, 1898. Forty sittings of ten minutes each. Slight dermatitis interrupted sittings for a time. Result, cure. Schiff[3] reports the case of a girl with two lupus ulcers. One ulcer healed in two months, the other in five months. Also, the case of a boy who was exposed one-half hour to one hour daily for ten days only. Nevertheless the therapeutic action continued, and the lupus was healed in four months without further treatment. Kümmell[36] has treated 16 lupus patients, in whom there was at least improvement in all but one. Cures in from four weeks to several months. He then states that the time elapsed is too short to claim too much as to results. Albers-Schönberg[7] reports 12 cases. He has had some returns, "but what procedure has not." Of these 12 cases he considers 7 absolutely cured. Several have remained free for over one year, and one for one and a half years. The opponents of this method of treatment, he says, will not consider a period of from nine months to one and a half years long enough. He looked with suspicion on the other 5 cases — some had returned, and all were unsatisfactory. Hall-Edwards[6] reports 3 cases, in only one of which was the result considered satisfactory, "due perhaps to defective procedure." Jutassy[4] reports 2 cases cured. In commenting upon the published cases he says, "that a large part of the lupus cases reported are still too recent to be judged. In about one-half of the older cases there has been a return." Many other cases have been reported as cured by the x-rays, but all are recent. The oldest cases which I have seen reported are those of Schiff, Gocht, Kümmell and Albers-Schönberg. These men have reported cases in which there has been no return in over one year, and a few cases in which there has been no return in two years. These cases are surely encouraging, but remembering the peculiar delayed healing as shown in the cases of dermatitis, and how slowly the changes set up are overcome, perhaps, as Jutassy has said, the time is still too short to allow of an absolute judgment.

The reaction of the lupus tissue to the x-rays is considered by Freund and Schiff to be characteristic. They describe this reaction as follows: The visible lupus nodules grow gradually dark red and turgid. Then there appear, on places apparently normal, dark spots, which gradually assume the characteristics of lupus nodules. Later the nodules fall out, leaving a hole the size of a pin's head, which looks as if it were made by a curette. In the place of the nodules are left fine subcutaneous scars. The intervening skin is white and smooth. Himmel concludes that the x-rays exert a greater and deeper action upon the lupus tissue than upon the healthy skin.

Lupus vulgaris and cases of hypertrichosis are the diseases in which the x-rays have been used therapeutically most often, but there are also several other diseases in which they have been used more or less.

A few cases of lupus erythematosus have been reported. Jutassy claims better results in the treatment of this disease from the x-rays than from any other treatment.

Gocht reports a case where hairs growing in a wound prevented healing. The hairs were removed by the x-rays, and the wound then healed. This use of the x-rays is similar to a suggested use in removing the hair in certain parasitic diseases, such as tinea, favus, etc., where a permanent removal is not desired, but merely a temporary removal, to enable treatment to be carried out more easily and effectively.

Before the French Academy of Sciences, on behalf of Dr. Sorel and Professor Soret of Havre, M. Mascat[39] showed a series of photographs of the hand of a patient who had been suffering from elephantiasis. The patient had recovered, and solely by the use of the x-rays, after three sittings of a few minutes each.

A few cases of eczema have been treated by the x-rays. According to Albers-Schönberg[7] the x-rays remove absolutely and surely the eczema accompanying lupus. Dr. Pusey[40] states that "the cases of eczema in which this method has a field of usefulness, are the very intractable cases of chronic eczema, in which there is a necessity for a marked stimulation of the skin, in order to get absorption of the inflammatory products." He concludes that the field of usefulness in eczema will be limited.

A few cases have been reported recently of the use of the x-rays in cutaneous cancer. Stenbeck claims to be the first in this field. He reports[41] a case of a woman with two ulcerations on the dorsum and right half of the nose. At first, daily sessions of ten to twelve minutes each were given; lamp distance fifteen to twenty centimetres. Reaction began after four sessions. After eight or ten exposures profuse suppuration ensued. After thirty-five exposures the ulcers began to look clean and smooth, the epidermal islets were cast off, and new epithelial tissue began to form. Treatment now began to be more vigorous, and the exposures were prolonged to fifteen minutes each, with the lamp at ten centimetres. A weak reaction appeared, but the newly formed epidermis was not affected. The greatest resistance was offered by the wall-like circumference of the ulcers. An entire month was required to overcome it. It decreased in height and width, and then broke up

into individual segments, which in time completely disappeared. Sequira [42] has reported a like case. Against these cases can be urged the same objection as against many of the lupus cases, time enough has not elapsed to judge of the final results, but even so, they are encouraging enough to warrant further trial.

Enough has been said to show the nature of the changes in the skin set up by the use of the x-rays and of the diseases in which advantage has been taken of these changes to apply them to therapeutic use. It remains but to speak briefly of the method of using the rays. The necessity of care to prevent injury has been spoken of already. To avoid such injuries Freund and Schiff have published a method of procedure which, if followed, they think will render the use of the rays perfectly safe. They state that for epilation without inflammation the maximum limit of strength of current should be 2 amperes; tension, 1½ volts; tube distance, 20 to 25 centimetres. The length of exposure should not be over ten minutes. To excite inflammation as in the treatment of lupus, increase the strength to 3½ amperes and the tension to 12¾ volts. Shorten the tube distance to 10 centimetres or less. Length of exposure should be the same. Protect the parts not to be treated with sheets of lead. To test the patient's resistance to the rays, give one or two test sittings with the tube distant 20 centimetres. If there is no reaction in three weeks, it shows that the patient can stand the treatment. All observers unite in saying that care is necessary, and that treatment must be suspended upon the first appearance of dermatitis. By observing these rules it is claimed that the treatment is rendered entirely safe; indeed, a number of men who have exposed hundreds of cases to the x-rays say that they have never had a case of dermatitis follow.

We may conclude: (1) That the real nature of the x-rays is not yet determined definitely, nor whether the therapeutic action following their use is due to the action of the rays themselves or of something of electrical origin accompanying them; (2) that the treatment is not without danger, unless the greatest care is used; (3) that the effects of the x-rays remain for a long time, and recovery is very slow; (4) that whatever may be the exact origin of the effects produced, a definite reaction is caused in the skin by the use of the x-rays; (5) that the changes induced in the skin are similar histologically to those seen in ordinary inflammation; (6) that the x-rays are not proved to have any bactericidal power; (7) that their therapeutic effect is probably due to the inflammation excited; (8) that hair can be removed by their use, and that lupus and several other diseases can be healed over; (9) that in a few reported cases we may fairly assume that a permanent cure has been effected, but that in a majority of the reported cases too little time has elapsed to rule out the possibility of a return of the disease; (10) that the effect of exposure to the x-rays is so extraordinarily slow in disappearing that months should elapse before an absolute cure is assumed; (11) that while the permanency of the cure effected may perhaps be doubtful as yet, it is certainly desirable to experiment further.

PATHOLOGY OF THE NEWBORN AS ILLUSTRATED IN THE PRACTICE OF THE WRITER.[1]

BY FREDERIC W. TAYLOR, M.D., CAMBRIDGE, MASS.

WHEN your president did me the honor to request from me a paper for this meeting, he suggested that it be clinical rather than scientific. Acting on this suggestion I have chosen to look over my records of obstetric cases with reference to the condition of the children.

The cases number in all 654, 563 being cases of which I was in charge, and 91 being cases at which I was present as assistant or consultant. I find that 64 — nearly 10% — of the children were abnormal either at birth or during the first few days of life, and it is a report of these that I present for your consideration tonight. All had been carried at least seven months.

[1] Read before the Obstetrical Society of Boston, January 15, 1901.

The classification which I have made is a purely clinical one. It is as follows: Children stillborn, 23; children born alive, dying within a few days, 22; children whose respiration was delayed, 10.

Of cases not included in these groups there are: deformity, 2; ophthalmia, 3; melena, 2; fracture of clavicle, same child as one melena, 1; depression in skull, 1; facial paralysis, 1.

Less serious conditions, as icterus and fungus of the navel were not noted.

Children stillborn. — Of the 23 stillborn infants 9 were delivered by forceps. In 8 of these cases the forceps were applied high. Four of these 8 cases required extreme force for delivery. The other 4 were delivered without difficulty; in 1 the cord was at the side of the head. In the ninth case the head descended well into the pelvis with occiput posterior, and did not rotate. The labor was long, about thirty-six hours. The mother's abdomen was very large and legs edematous. The urine examined two weeks before labor contained no albumin. The quantity of liquor amnii was estimated to be 6 quarts. The entire body of the child was very edematous, and the abdomen much distended. The placenta was adherent over its whole extent, and was very large and spongy. The cause of the edema of the child was not apparent. If maternal it must have been a temporary condition, as previous children, 6 in number, had been healthy, and the mother gave birth to healthy twins in less than thirteen months after this delivery. Two of the 23 stillborn children were delivered only after the head had been crushed. In each case the mother's pelvis was narrow. One child was turned with the expectation of extracting it alive. This proved to be impossible. The child died during the unavailing efforts to deliver the head. The other child died probably thirty-six hours before delivery. It weighed 10 pounds without the brain. The cause of its death was not discovered. The only abnormal condition of the mother, beside the narrow pelvis, was an acute universal eczema which began about ten days before the labor.

In 2 cases the position was transverse. In each the physician on his arrival found an arm presenting and the membranes ruptured.

In 2 cases the mothers were uremic, but had no convulsion. One of the children was delivered spontaneously, the other by podalic version. In the latter case the cord was pulseless when the hand was introduced into the uterus. Therefore in neither did operative interference cause the death of the child. The uremia of the mothers is the only condition that was apparent that would act unfavorably on the children.

An abnormal placenta existed in 3 cases. One was fatty; a second was large and contained an unusually large proportion of connective tissue. In this case the mother had mumps when several months pregnant. The attack was followed by extreme tenderness in both ovarian regions. The third placenta was hard, white and thin over more than half its area. In each case the delivery was premature.

Antepartum hemorrhage occurred in 1 case, beginning fifteen hours before delivery, and continuing eleven hours. It was probably the cause of the child's death, although fetal movements had not been felt for seventeen hours before the appearance of the flow which was synchronous with the onset of labor.

In 2 cases in which macerated children were born, one at seven and one-half months, the other at nine, the mothers had each been pregnant twice before, but had never borne healthy children. One had been delivered at six months and at four months; the other at eight months of a dead fetus, and at nine months of a child that lived only a few minutes. The reason for this habit did not appear.

Of twins born at full term, estimated to weigh 6 pounds each and apparently well developed, the epidermis was freely exfoliating from one, and there were blisters on the fingers of the other. Here also no cause of the deaths was discovered. The mother had previously borne one living child, and had miscarried once.

Children born alive but died. — The number of children born alive but dying within a few days of birth were 22. Eight were born naturally and showed no cause of death except a lack of vitality. One of them was born at seven months, 2 at seven and one-half months, and 3 at 8 months. The other 2 were probably also premature, although the length of the pregnancy was not known. They were both small. One weighed 4 pounds and 3 ounces; the other was not weighed. Three of the 22 were delivered by forceps, which were applied high in 2 cases, and low in 1. One child delivered by high forceps was apparently healthy, weighed 8¾ pounds, but lived only three days. The mother found it dead soon after she had nursed it. I suspected that it accidentally smothered in the pillow on which it was laid. The second, delivered by high forceps and traction rods, had the cord twice about the neck. Artificial respiration induced a few gasps only. The mother was edematous but not albuminuric. In the third case the head was in the vagina when forceps were applied, and extraction was not difficult. The child lived five days. It appeared perfectly well until the fourth day. Then at intervals respiration became feeble and slow, and the child cyanosed. On the administration of stimulants respiration improved, and the color became good. These attacks increased in frequency and severity until death. A careful post-mortem examination of head and trunk by Dr. E. A. Darling and myself revealed no lesion, and I am at a loss to explain the condition. In the cases of 5 children, 2 being twins, the mothers were uremic. One of the 5 was born at seven months. The mother had post-partem convulsions. The twins, also born at seven months, were extracted by the feet after manual dilation of the os. One lived a few minutes. It had been laid one side on the supposition that it was in good condition, and was found dead with much blood escaped from the cord. The other lived a few hours. The mother had vomited for eleven

days previous to the labor, and continued to do so till she died. The autopsy of the mother revealed advanced chronic parenchymatous nephritis. In the fourth case the mother had convulsions several weeks before labor and again during labor. The os was dilated manually, the child was delivered by turning, and lived a few hours. In the fifth the cord was tight about the neck, but offered no serious resistance to delivery. The fetal heart was plainly heard in the early part of the labor, but the cord was pulseless at the time of delivery. The child gasped only a few times. Labor had lasted fifteen hours; delivery was spontaneous.

One mother of twins was in an advanced stage of phthisis. The children were born at eight months, and died within two days. One child developed purulent inflammation at the navel and died, aged five days. The source of the infection was not discovered.

There was one case of hemorrhage from the navel. There was no history of hemophilia in the parents or in an older child. The delivery was by breech, but was successfully accomplished. The cord was unusually long. The labor lasted only four hours. The child, a boy, was well till the morning of the fourth day. It was then reported to have fretted during the previous night and to have had two black dejections. A few stains thought by the nurse to be blood were on the napkin. The child was pale and listless. At noon it had a convulsion, and in the evening I was shown two napkins considerably stained with blood, and found the belly band which was then on extensively stained and the napkin somewhat, and the cloth about the navel saturated with blood. One or two lines from the line of demarkation of the cord from the skin was an excoriated line on the skin a quarter to a third of an inch long. The proximal part of the cord for a third of an inch was full, soft and moist. The child was pale, and cried feebly. Bleeding stopped on removal of the coverings. The next morning profuse bleeding again occurred, and in place of the excoriated line seen the day before there was a granular surface one to two lines wide, extending two-thirds the circumference of the navel. The child was pale and cold, and died at noon without recurrence of the bleeding.

There is 1 case of deformity of the esophagus and trachea. The child cried normally immediately after birth, but within two or three minutes the breathing became hoarse and squeaky, as if obstructed, and the epigastrium and suprasternal depression were deeply retracted during inspiration; then respiration ceased, and the child relaxed. Then came a discharge of perhaps 2 drachms of yellow frothy mucus from the nose while the head was dependent. Respiration returned, and was clear. In a few minutes, however, it was again obstructed, and then cleared in the same manner as before. Later an attempt to feed the child was followed by an attack of dyspnea and discharge of liquid through the nose. A bougie passed through the nose met an obstruction 5 inches from the nostril. The child lived less than two days. An autopsy was made by Dr. Wm. D. Swan and myself. A bougie passed into the esophagus was arrested at the same point as during life. A short distance below the level of the cricoid cartilage the trachea and esophagus were firmly joined by connective tissue. The upper part of the esophagus was a blind pouch. The lower part communicated at its upper end with the trachea by an opening about a line in diameter. Above this opening, on the posterior wall of the trachea, was a shallow groove.

Another case of deformity, a meningocele, was seen with Dr. E. A. Darling, who discovered by vaginal examination that the fetus was abnormal, and feared difficulty in delivery. The tumor was pedunculated, the size of an orange, and attached at the posterior fontanelle. On the under side of the pedicle was a small opening from which a liquid drained constantly. The temperature rose to 107° F. on the second day, and death occurred on the third. The tumor contained cerebrospinal fluid and brain tissue. The cerebral hemispheres were small, and the corpus callosum absent.

Delayed Respiration. — In 10 cases there was sufficient delay in respiration to cause the fact to be noted, while not enough to prove fatal. In one of these the cord was twice about the neck; in another once, and so short that it was necessary to cut it before the shoulders could be delivered. It is probable that tension on the cords had sufficiently interfered with fetal circulation to cause asphyxia and consequent delay in respiration. At least no other cause was evident. In 6 cases the children were delivered by forceps, 4 by high, and 2 by low. These 6 labors were all long, from sixteen hours to four days, and ether was used for a considerable time. In the other 2 delivery was by podalic version. Both mothers were uremic; one of them died of eclampsia. In the case in which the mother died the delay in the establishment of natural respiration was so great that it deserves detailed notice. The mother, a primipara, was within a few days of the expected time of confinement. Symptoms of uremia appeared ten days previous, increased in spite of treatment, and culminated in blindness and convulsion. Labor had not begun. The os was dilated forcibly and the child delivered by podalic version. Dilatation and delivery occupied three-fourths of an hour. Delivery was not difficult. The child was cyanosed; the heart beat feebly about 100 a minute. After a few minutes of artificial respiration the child gasped 4 to 6 times a minute. The treatment consisted of baths of warm water alternating with sprinkling of cold, rhythmical traction of tongue, suspension by feet, artificial respiration — both the Sylvester and the Schultze methods. At the end of half an hour the pulse was 25 to 30, the respiration 4 to 6, gasping, the color not improved. Dr. Geo. P. Cogswell, who was assisting me, then began slapping rapidly and vigorously all parts of the child, head as well as trunk and limbs. In fifteen or twenty minutes the heart beat was 80 and the gasps 15. Every

remission of slapping was followed by feebler action of heart and lungs, and renewal of slapping by stronger action. Gradually the skin became mottled pink and white, and there were a few feeble cries. An hour and a half after birth, till which time this treatment was continued, the heart beat was 120 and the respiration 20, and persisted without treatment; the color was good. The child subsequently showed no ill effects of the heroic treatment. For some weeks it did not gain weight, but later throve fairly, and when ten months old was reported to weigh between 17 and 18 pounds. When this child had repeatedly ceased to breathe as soon as vigorous treatment was withheld, I despaired of its life, assuming that a condition or lesion existed incompatible with life. Its resuscitation was to me unexpected, and may be ascribed to Dr. Cogswell's patient and enthusiastic efforts. One naturally asks what pathological condition was removed thereby. Is it not fair to suppose that in addition to asphyxia the child was suffering from uremia received from the mother, and that because of this, respiration and heart action could not be maintained except under the influence of excessive stimulation, and that during the hour and a half during which such stimulation was applied, elimination through skin, lungs and kidneys had been sufficient to bring the blood and tissues into a condition near enough normal to permit vital processes to continue spontaneously? But whatever the explanation, the result encourages longer and more energetic efforts than I believe most of us are accustomed to make in behalf of children born under similar conditions.

Deformity. — Beside the cases of deformity included in the second group, and already described, there are 2, one of hare lip and cleft palate, about which there was nothing unusual, and one of vascular nevus. The nevus was of the capillary variety. It was on the left side of the face, and made that side more prominent than the other. When the child was only a few weeks old, his mother noticed that he did not move the right hand as freely as he did the left. When five months old he screamed an hour, and then had twitching of the right leg. Subsequently he had many attacks of screaming and convulsion. The convulsion usually began in the right eye, and slowly extended over the right arm and leg. He is now seven and one-half years old, walks with a slight limp, and has but little use of right arm and hand, which are small. He is undersized, and poorly developed mentally. A recent examination shows that the nevus occupies the left cheek, left half of forehead, of nose and of upper lip, and appears irregularly on the palpebral conjunctiva of the left eye, the inside of the left cheek, and the left half of the palate. This distribution corresponds to the distribution of the ophthalmic and superior maxillary branches of the fifth cranial nerve, a correspondence which has been noted in other cases. If abnormal vascularity has followed also the distribution of the dural branches of the superior maxillary branch, have we not a reasonable explanation of the convulsions and paralysis in the pressure which would naturally be exerted by the very vascular tissues on the motor areas?

Ophthalmia. — Three cases. None of them was of a very severe type.

Melena. — There were 2 cases. A girl, weighing 10 pounds, was born after a pregnancy of ten months. The father had had severe attacks of epistaxis during boyhood and youth. Otherwise the family history is negative. The labor was normal, except that delivery of the shoulders was difficult, requiring strong traction on the head in addition to the expulsive efforts of the mother. During traction the right clavicle broke near its outer end. The child was born at 2.30 A.M. During the following day and night she was in much distress, crying, choking and vomiting frequently. The vomitus consisted at times of brown mucus, at times of bright red blood. The junction of the umbilical cord and skin was of a slightly yellow color, of sodden appearance, and had a red areola. The yellow ring was snipped with scissors, but no pus exuded. On the second day vomiting of the same character as on the first occurred three times, and in the following night once, but not afterwards. On the fourth day the navel had a much better appearance. On the fifth a bloody vaginal flow began, and lasted four days. Vaginal examination, by means of an aural speculum, discovered the blood coming from the uterus. The cord came off on the ninth day leaving the navel normal. The temperature reached 100° F. on the second day, 101.8° on the third, and 100.2° on the fourth, and was afterward normal. The digestion was poor for several weeks, but good since then, and the child has developed satisfactorily. The clavicle united without deformity.

The other child, a boy, weighing 6 pounds, had no family history of hemophilia. The mother had serious mitral insufficiency. All over the child's head there were at birth dark reddish-brown spots, the size of an ordinary pin head, thickly placed, not disappearing on pressure. When twelve hours old he vomited dark green mucus, and did so repeatedly till the third day when he vomited 1 or 2 drachms of bright blood, and passed dejecta, the first tarry in appearance, later red and black, or dark red. There was frequent spitting of a substance streaked with blood. On the fourth day he had twelve dejections red or black. After one large one consisting of dark red liquid the extremities became cold, the face cyanosed, and the whole body limp. This condition lasted three-fourths of an hour. On the fifth day there were six dejections of the same character as before, but less in amount; vomiting of a small clot, followed by faintness. There was no further hematemesis. There were four black or red dejections on the sixth day, one on the eighth, one on the ninth, and a green one on the tenth. The temperature varied from 97° to 100°. In two weeks the macules had nearly disappeared. The child remained small, but a year afterwards was living, and considered by the mother to be well.

Depression in skull and facial paralysis. — In the 2 following I believe that the lesions were caused by the forceps. One child was born with a depression in the left frontal bone, 1 by 1½ inches, and ½ inch deep. Within four weeks the bone had returned nearly to its normal contour. The delivery was by means of forceps and traction rods, and considerable force was required. The other child had left facial paralysis, which had so diminished by the eleventh day as to be hardly perceptible. Forceps had been applied when the head was well in the pelvis, with occiput R. A.

I am aware that in this recital of cases there is much that is commonplace, and that from your own experiences, which in obstetrics are larger than mine, you could contribute cases of equal and greater interest. If, however, any of us shall be stimulated by it to more careful observation of the lesions and symptoms of the newborn child, this paper will have a sufficient excuse for being.

OBLIQUE SUBTROCHANTERIC OSTEOTOMY, FOR THE LENGTHENING OF THE FEMUR, AND CORRECTION OF THE DEFORMITY OF FLEXION RESULTING FROM HIP JOINT DISEASE.

BY E. G. ABBOTT, M.D., PORTLAND, ME.

OSTEOTOMY, for the correction of flexion in hip disease, has been performed in various ways on different parts of the femur, for more than a half century, and the results obtained have justified its recommendation in the majority of cases, but until recently no attempt has been made to combine lengthening of the bone with the straightening of the limb.

The earliest operators divided the bone above the trochanter major, or at least above the trochanter minor, meeting with sufficient success to warrant the continuation of experiments in this direction.

Adams' section of the neck of the femur is familiar to all, and from an anatomical standpoint it is certainly correct, but in a large percentage of cases cannot be successfully accomplished, as the neck is absent in many, while in others the pathological changes are so marked that the part is inaccessible.

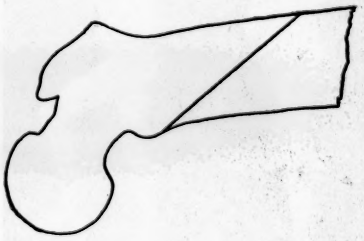
Barton, Sayer, Maisoneuve and others performed the osteotomy lower down, but still above the trochanter minor, and this operation, although much less difficult than Adams' had the same disadvantage of being above the attachment of the ileopsoas muscle, which often caused a return of the flexion.

Volkman's operation, which consists of the removal of a wedge-shaped piece of bone from the trochanter major, offered no improvement over the others, and though reported successful, received but little support, soon falling into disuse.

In the year 1872, Gant devised the operation which bears his name, and the advantage gained by setting free the resistance of the contractured ileopsoas muscle, was at once recognized, and has been almost universally used since. Although this operation removes many of the objectionable features found in the others, it still leaves much room for improvement, and while the flexion is permanently remedied, it causes a considerable shortening of the bone, necessitating the wearing of such a thick patten that it makes walking in many cases, nearly as difficult as before.

Hoffa, Lauenstein, Landeve, König, and other German savants, during the past year have successfully performed the oblique subtrochanteric osteotomy with lengthening of the femur, and strongly recommend it in preference to the so-called Gant operation. A brief outline of their procedure is as follows:

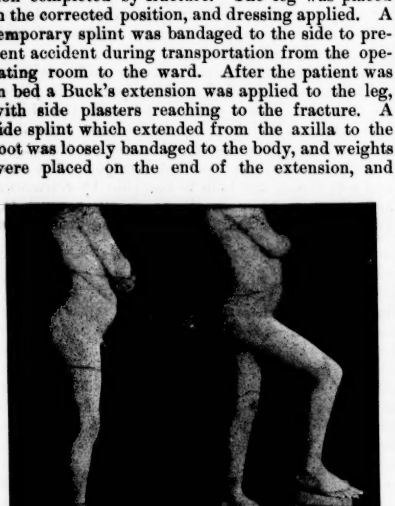
All of the contractured muscles and fasciæ are subcutaneously divided, and the patient is placed on the side, with a cushion between the thighs. The femur is laid bare by an incision some 3 inches in length, the centre of which is from 2½ to 4 inches below the trochanter major. The skin and soft tissues are held to one side by retractors, and the osteotome is placed firmly against the bone, and driven at an angle, varying from 30° to



45° upward and inward through the shaft of the femur until only a thin bridge of the inner, compact tissue remains, when the division is completed by fracture. The leg is then forcibly extended by means of a screw, drawing the smooth-cut surfaces by each other, until the desired length is obtained. The wound is dressed without closing, and a plaster of Paris spica is placed on the leg with an opening over the incision, allowing easy access to it. The leg remains in this position five weeks, after which the plaster is removed, and massage and gymnastics employed, the patient meanwhile moving around with the aid of crutches, the full weight not being borne on the fracture before the twelfth week.

In undertaking this operation the writer felt that it might be much simplified by obviating the use of such powerful force in the separation of the bone, and the destruction of so much of the soft tissues subcutaneously, thereby reducing the liability of infection and injury to the blood vessels and nerves. A description of the method employed by him on a patient where flexion of 45° and actual shortening of the bone amounting to 3½ inches were present, is given below:

The site of the operation was prepared in the usual manner, and the patient placed on the side with a large sand bag between the thighs against the perineum. The osteotome, which was of the same width as the bone, was entered through the skin, and underlying tissues, upon the femur about 4 inches below the upper border of the trochanter major, where it was firmly held at an angle of 30°. It was then driven through the bone as far as the inner compact tissue, when it was exchanged for a narrow one, and the division continued well into this, after which, it was withdrawn and the section completed by fracture. The leg was placed in the corrected position, and dressing applied. A temporary splint was bandaged to the side to prevent accident during transportation from the operating room to the ward. After the patient was in bed a Buck's extension was applied to the leg, with side plasters reaching to the fracture. A side splint which extended from the axilla to the foot was loosely bandaged to the body, and weights were placed on the end of the extension, and



gradually increased. The muscles relaxed in thirty-six hours, when the length and position were regulated and the splint firmly applied, retaining the leg in the corrected position. Measurements were frequently made in order to ascertain if the length remained unchanged, and at the end of the eighth week all apparatus was removed, and the patient allowed to move around in bed. At the commencement of the tenth week he was given crutches and exercised freely. The femur was lengthened 1½ inches, by actual measurement, and the flexion was completely corrected, as the adhesions were broken up by the operation, allowing movement of 15°. Recovery was uninterrupted, union being firm at end of eighth week, and the patient now walks easily with the heel of the shoe raised ¾ of an inch on inside. There are several steps in the operation which the writer considers of importance, and which should be brought to the notice of the surgeon:

Too much stress cannot be laid upon the advantage of making a radeograph, which will enable him to determine the size of the femur, and the exact location at which the osteotome should be entered in order to free the attachment of the ileopsoas muscle to the trochanter minor.

Another point to be considered is the width of the osteotome, which must be regulated by the size of the bone, so as to obtain a clean cut surface by one passage of the instrument. The angle at which it is to be held must also be governed by the size of the femur.

It will be found necessary to use judgment rather than any hard and fast rule in regard to the amount of weight necessary, as it varies with different patients, and must be gradually increased until results are obtained when it can be lessened and held by the side splints.

Clinical Department.

A CASE OF CHIN LEFT POSTERIOR.[1]

BY H. T. SWAIN, M.D., BOSTON,
Physician to Out Patients, Boston Lying-In Hospital.

MRS. A. P., an Italian, thirty-two years old, in her third pregnancy. Previous history negative. Previous labors normal.

When I first saw the patient in the Out-Patient Department of the Lying-in Hospital, November 15, 1900, at 8.30 P.M., she had been in labor about six hours, the membranes having ruptured three hours previously. She did not send for a doctor until she had been in labor for some time, and when first seen by the externe the head was so low that he easily made a diagnosis of face, sending at once for assistance. When seen by Dr. Cary, the out-patient house physician, the presenting part was only a little higher than the position in which I shall describe it.

Abdominal examination showed the back to be to the left, fetal heart loudest in the lower left quadrant, rate 130. During each pain the uterus contracted firmly, and the abdominal muscles were rigidly set, the patient straining violently. The intervals of the contractions were about two minutes, and they lasted a good minute. Visual examination showed considerable bulging of the external genitals during each pain.

Vaginal examination showed the os fully dilatable, membranes ruptured, and a face presenting about one and a half inches from the introitus, with the chin left and posterior. During a pain the head descended very little. There was not the least rotation. What little was gained during the pain was lost in the interval, for the head receded immediately. I tried during two or three pains to rotate the head by pressure with the hand against the posterior ramus of the lower jaw, but was unable to accomplish anything, the head being firmly wedged into the excavation. Dr. Cary's attempts

[1] Read before the Obstetrical Society of Boston, January 15, 1901.

to flex, and then to extend and rotate had been without result.

The patient was now given full surgical anesthesia, and pressure with the hand, and then a single forceps blade failed to rotate in the least. The forceps was then applied and rotation attempted, some traction at the same time being used. However, the head being so firmly wedged in, the forceps could not be well enough applied to allow much pull, and even had I been able to get a firm application, I should not have felt like pulling much because it was evident that the unrotated head could not come down without great violence to the soft parts. I was unable to turn the head in the least by any of the methods mentioned after careful trial. I knew the child was alive, for every time that I accidentally touched her lips she sucked my finger. I disliked to think of perforation under these circumstances.

Making another attempt at manual rotation after taking off the forceps, I noticed that, while pulling hard under the chin to increase extension, the head seemed to recede a little. Following this lead, by extreme extension, the middle finger under the chin, the thumb against the forehead, and gentle pressure upward, the head was gradually slid up, and placed above the brim between an assistant's hands holding it through the abdominal wall. I then wondered as to the next step. I knew that a speedy delivery was essential to the child's life for the cord was pulsating feebly. I felt that it would be hard to bring the head down with the occiput presenting because of the extreme moulding and because the forces which made it come down as a face, would still be likely to extend the head. Feeling a foot without putting my hand above the lower uterine segment, I brought it down, my assistant turning the head up at the same time. Delivery was easy as a half breech.

The child resuscitated with some difficulty. Her face was extremely cyanotic and edematous, the lips, eyelids, and nose bulging a great deal. There was a complete subconjunctival ecchymosis in each eye. The baby weighed nine pounds, and is now well, although there is still a noticeable retraction of the head. The mother was uninjured and had a normal convalescence.

Other methods of operation have been advised. McLean, in two cases, has converted a posterior chin to an anterior occipit in the pelvis. In this case the large moulded head so filled the pelvis that it would have been necessary to disengage it before turning.

Symphyseotomy has been advocated.

I realized the dangers of replacing the head above the brim, and turning in a dry uterus, and should not have used force to accomplish them. It seems to me that the ease with which the head pushed back was due to the fact that the patient, by her own muscular force, had crowded the head down and that the uterus was not in the state of retraction that it would have been, had it been forcing the head down.

I shall attempt to draw no conclusions from this single case. It is interesting to me as showing how easily a head well down in the pelvis in a position impossible of delivery without violence, could be replaced above the brim. It was interesting also as showing the impossibility of the commonly accepted mechanism in this case, for while the head was so far down that it could advance no farther without violence, the chin was not impinging against anything.

Medical Progress.

RECENT PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

(Concluded from No. 14, p. 335.)

WATER SUPPLY AND SEWERAGE.

A Process for Removing Iron from Water.

Messrs. Linde and Hess[24] describe a process for removing the iron from water by treating it in a filtering vessel filled with wood shavings free from turpentine, and impregnated with oxide of tin. The hydrated oxide of iron resulting from this process is retained by the shavings as a brownish red deposit. The shavings are renewed every two months.

Schumburg's Process for Purifying Water.

Pfuhl[25] states that this process consists in adding .06 gramme of free bromine in the form of bromide of potassium solution to each liter of water. A like volume of 9% solution of ammonia is added to remove the bromine and make the water palatable. This process is advocated for use in the case of suspected waters, epidemics, ships' tanks and armies in tropical countries.

Septic Tanks for Sewage Disposal.

Messrs. Alvord & Shields,[26] of Chicago, in commenting upon the use of septic tanks for sewage disposal, make the following statement:

"A good deal of this enthusiasm has arisen because of the unwillingness of experimenters to publish their failures, or in any way record experiences which did not come up to their expectations. The literature on this subject is oftentimes misleading, and must be read in the light of personal examination or practical experience to be of any benefit. As a sample of the overconfidence now being displayed, the interesting proposition of a village has been noticed which intends to place its septic tank and contact beds in a public park overlooking a beautiful lake, floor it over, and provide seats so that it may become a playground for the misses and children of the neighborhood, and a resting place for the pleasure seeker. Such overconfidence has arisen from repeated statements in print that no nuisance results from the process. The statement is not

[24] Ges. Ingenieur, April 15, 1900, p. 105.
[25] Zeitsch. f. Hyg., 1900, p. 53.
[26] Engineering Record, March 16, 1901, p. 247.

untrue, in general, but one who had visited or operated many of these tanks would not recommend them for sites for lovers' rests or health retreats unless given the most expert management and attention. The writers have operated several septic tanks during the past three years, one of which has had close attention during the whole of that time. The first season it was thought a simple affair to manage it; the second season it was concluded nothing was definitely known about its operation at all; the third season, in humbleness of spirit, it was realized that something was being learned about it, and in the course of another season it is hoped to learn even more.

. . . . . .

"How is it then that a septic tank of fixed dimensions succeeds at all, as in so many cases they unquestionably have, and why are some of them such undeniable failures? We think it is, so far at least, purely a matter of chance. One septic tank has been observed which was carefully designed, which has given as high purification as 80% of organic matter removed; while another tank of the same design in a neighboring city of the same size, with about the same quantity of sewage and with details almost precisely the same, has not effected so good purification, perhaps not half as good, on the average. If this is true in such an instance, how is it possible that tanks hitherto used for chemical precipitation or cisterns hitherto used for pumping reservoirs, are going to be turned into successful septic tanks at a moment's notice, and for all kinds and quantities of sewage?"

London Sewage.[37]

The following figures relate to the sewage of London which was treated in 1900 at the two outfalls at Barking and Crossness upon the Thames:

	Barking. Gallons.	Crossness. Gallons.	Total. Gallons.
Sewage treated,	58,209,600,000	43,321,200,000	101,530,800,000
Maximum daily flow,	316,202,400	215,958,074	
Minimum " "	87,372,000	77,547,948	
	Tons.	Tons.	Tons.
Lime used,	12,999	7,455	20,454
Sulphur, iron,	2,918	2,011	4,929
Sludge sent to sea,	1,574,000	798,000	2,372,000
Average per week,	30,270	15,346	45,616
Screenings,	4,176	813	4,989

The increase in the quantity of sewage treated, over that of the previous year was 8,315,023,000 gallons, and in the quantity of sludge sent to sea 82,000 tons.

INDUSTRIAL HYGIENE.

Industrial Lead Poisoning.

Dr. Legge, Medical Inspector of factories for England, contributes a paper[38] on Lead Poisoning, the data for which were tabulated as the result of a law of 1893, which requires every physician when called to a patient whom he believes to be suffering with lead poisoning, contracted in a factory or workshop to notify the case at once to the inspector of factories. A similar obligation is imposed upon the occupier or owner of the factory, thus constituting a close analogy between this law and that which requires notification of infectious diseases. As one main object of an infectious disease notification act is the protection of the community against such a disease as diphtheria, so repeated notifications of lead poisoning in the same trade may lead to an investigation, and to the adoption of regulations for the protection of the operatives.

The principal symptoms referable to lead poisoning were those of the digestive system, anemia, headache, paretic, encephalopathic, rheumatic and uterine.

The occupations were the following: smelting, brass working, sheet lead, printing, file cutting, plumbing, enameling of hollow ware, white lead working, red lead, earthenware, lithotransferring, glass, enameling of iron plates, electric accumulators, paints and colors, coach painting, ship building and other industries.

The methods of exposure varied, but were chiefly to the fumes, the dust, and the handling of metallic lead and paint.

The writer urges the importance of cleanliness, and not simply cleanliness of the hands, but also of the teeth, nails and clothing.

He also insists upon a periodic medical examination of workmen, by a competent medical examiner who should have power to suspend any one temporarily, or permanently, from work whom he may find is specially susceptible to poisoning.

This examination should include thorough inspection of the condition of the teeth and gums, of the pupils and muscles of the eyes, the color of the conjunctiva, the presence or absence of tremor or hysteria, and the resistance of the extensors of the wrist to forcible flexion.

A table is presented relating to 1130 cases of lead poisoning which were reported in 1899. It does not include cases reported among painters and plumbers, since the acts do not apply to these occupations.

The Dangers of Cutlery Grinding.

Dr. Moritz, of Solingen,[39] presents a statement of the dangers to which knife-grinders and those employed in similar occupations are subjected. The mortality of men employed in this work over twenty years of age, is three times as great as that of the general population of the same ages. Men in such employment rarely live to the age of fifty. The author, after examining 1,250 employés in such work, found only 16% in a healthy condition.

This industry has increased in Solingen from 1,581 workmen in 1860 to 4,027 in 1898, notwithstanding the danger to which they are exposed. The dust consists not only of the steel dust from the knives, scissors, razors, etc., but also the dust of the mill-stones upon which they are ground, which are reduced in size one-half in four weeks' usage.

The mortality from diseases of the respiratory organs among these workmen constitutes 72.5% of the total mortality, as compared with 35.3%

[37] Engineering Record, March 16, 1901, p. 246.
[38] Journal of Hygiene, vol. 1, No. 1, 1901, p. 96.
[39] Central b. f. allg. Gesundheit, 1900, p. 283.

for other occupations of the same ages. The prevention of these dangers is accomplished to some extent by moist grinding, covering the mill-stones, aspiration of the dust by various forms of apparatus, providing cuspidors, prohibiting alcoholic liquors, prescribing baths and personal cleanliness.

Dr. Rompke, of Solingen,[30] contributes a paper on the subject, in which he compares the workmen at Solingen with those at Sheffield, England, in the same industry. He compares the advantages and disadvantages in each place, and says the mortality from diseases of the chest among the grinders at Sheffield is only 61.7% of the total as compared with 72.5% among the same class of workmen at Solingen. He attributes this to several causes, among which are the position of the body while at work, the absorption of less dust at Sheffield, more regular habits, and better housing.

The Gannister Disease.

Birmingham describes this disease as produced in gannister works, or establishments for the manufacture of bricks from a hard, compact material occurring in clay. It is so hard as to require blasting, and is ground in mills. Its manufacture is attended with fine dust, the breathing of which leads to the formation of fibroid tissue.

The mortality among gannister miners is 42 per 1,000; among grinders, 180 per 1,000 and among brickmakers, 22 per 1,000. The author advises as methods of prevention: (1) The employment of adults only. (2) Medical examination before beginning work. (3) Medical examination every 3 months. All employés having bronchitis to stop work until recovery. (4) The use of respirators. (5) Frequent inspection of works. (6) Automatic machinery when practicable. (7) Use of water to allay dust. (8) Efficient ventilation.

Immunity of Oil Merchants to Plague.

Soir[31] noticed that workers in oil do not contract plague. He experimented with rats. Taking a rat from a house infested with fleas, he killed it and placed it in a cage with two other rats. The skin of one of these rats had been oiled and the other left in its normal condition. All the fleas migrated to the body of the dry rat, not one being found on the oiled rat. To this aversion of fleas to oil he thought it probable the workmen owed their immunity to plague. Galli-Valerie[32] came to similar conclusions relative to the rôle played by rats and fleas in spreading plague.

MUNICIPAL SANITATION.

Street Oiling as a Health Measure.

One of the greatest foes to good health, both indoors and outdoors, is dust; not only on account of its irritating qualities when taken into the air passages, but also on account of its property of transmitting infection. Any measure like street watering which will prevent dust from rising into the air is a health measure.

[30] Viertelj. f. gericht. med. u. öff. Sanitatswesen, October, 1900.
[31] Rev. Scien. March 31, 1900.
[32] Central b. f. Bakt. January 6, 1900.

Recently, on some of the principal railway lines, petroleum has been successfully employed for the purpose of making railway travel in the summer more comfortable and less inimical to the health of the passengers.

Mr. O. W. Longden[33] discusses the subject of oiling roads in Los Angeles, California, a dusty region where the water supply in summer is deficient. The experiment was first tried in 1898, upon six miles of road. In 1900 fifty miles were oiled. He concludes that well oiled roads are practically dustless, and that such roads are a boon in any country.

The demand for dust-free roads is increasing. The superiority of oiling over watering consists in the lower cost of oiling, and in the fact that it can be used in places where water cannot be had as in a country with deficient rainfall. Oiled roads are free from dust in summer and from mud in winter, and require only two or three applications of oil in the first season. About 60 barrels of oil per mile were used for a space 12 feet wide, on the first application. The second application required about 40 barrels per mile, and the third still less.

The oil cost from $1.10 to $1.25 per barrel, and 25 cents for delivery, the total cost being about $150 per mile for a season. There is a disagreeable odor at first, but this is not permanent.

Underground Bakeries.

In five districts of London[34] there are 315 bakeries, of which number 245 are situated underground.

The city of Manchester, England, has 514 bake houses, of which 207 are underground. It appears to be a common practice for a baker to rent a house and convert the cellar into a bakery.

According to Dr. Walsh, "the larger part of the national output of breadstuff is prepared in premises that would not be passed as fit for slaughter houses."

(An underground bake house should not be tolerated. On the contrary, the preparation of this most important article of food should be conducted under strict sanitary conditions, namely, abundance of light, good ventilation, absence of rats and all other vermin, and above all absolute cleanliness in every department of the work. It is also quite as essential that the workmen should be entirely free from every kind of infectious disease, as it is in the case of the production and sale of milk. — EDITOR.)

Baths and Bathers in London.[35]

Under the Baths[35] and Washhouses Acts, 2,532 public baths are in existence, 887 first class, 1,659 second class, and 85 swimming baths. The total number of baths in 1897–1898 was 4,463,109. The finances showed a deficit of £83,360, or $333,000.

[33] Engineering Record, November 24, 1900, p. 490.
[34] The Fabian Tracts, No. 94, London, December, 1900; see also a paper on the same subject by Dr. E. W. Hope, medical officer of health of Liverpool, in the Sanitary Record of August 31, 1900.
[35] Returns of Local Government Committee of the London Council, November 21, 1899.

HOUSEHOLD HYGIENE.

The Effect of Air Moisture on the Health of Persons in Enclosed Spaces.

Many sanitary experts still retain a belief in the necessity of a large ratio of watery vapor in the air of apartments, in order to provide for the comfort and health of the inmates. In many plans for ventilation it is customary to arrange artificial means for moistening the air; and unless great care is taken in attending to these appliances, their use entails many disadvantages. The author, Nussbaum,[36] maintains that in the case of rooms in which the temperature reaches 20° C, artificial means for providing moisture in the air are unnecessary. His observations, which agree with those of Wolffhügel, have led to the belief that dry air in which the vapor reaches only 30% of complete saturation is in every way better than air saturated with moisture. Several authorities are cited in support of this opinion. It is plain that the degree of moisture necessary to insure comfort depends in some degree upon the temperature of the surrounding air, and hence it is useless to specify a fixed amount of moisture to satisfy all conditions. At the normal indoor temperature from 40% to 60% of saturation suffices; but for hot rooms and in cases where much exertion is necessary, this degree of moisture may be diminished 10%.

It is possible that it will generally be better to dry the air required for ventilation rather than to moisten it, because the superfluous moisture may be deposited on cold surfaces, and thus afford lodging for dust and micro-organisms.

Damp air may be regarded as unwholesome, and hinders the healthy action of the skin.

Carbonic Oxide in Dwelling Houses.[37]

The discussion relative to the poisonous qualities of water gas which began in America nearly twenty years ago, and was followed by a parliamentary investigation in England, is now being taken up in Germany. Dr. Sachs alludes to the fact that the deaths from this gas usually occur in enclosed spaces and also commonly in dwellings. These deaths also usually occur from mixtures of gas with the air in which the volume of the gas is often very small. He discusses the various measures necessary to prevent the different sources of danger, and shows that the evils arising from the use of water gas are so great as to have induced experts to advise that its use in dwellings should be prohibited.

VITAL STATISTICS.

Reduction in Death Rate.

Dr. Corfield, in an address delivered at Paris before the French Society of Hygiene,[38] shows that the death rate of London, as well as that of England and Wales, has fallen as follows, coincident with the enactment and execution of sanitary laws:

LONDON.

	Average Death Rate per Annum.
1851-1870	24.1
Nuisance Removal Act, 1855. Sanitary Act, 1866.	
1870-1890,	22.5
Public Health Act (London), 1891.	
1891-1895,	20.2
1895-1899,	18.8

ENGLAND AND WALES.

1849-1875,	22.4
Public Health Act, 1875.	
1876-1880,	20.8
1881-1885,	19.4
1886-1890,	18.9
1890-1895,	18.7
1896-1898,	17.4

ENGLAND AND WALES.

Annual Death Rates per Million Living.

Vital Statistics of Prussia.[39]

The close of the century and the celebration of the bicentenary of the Kingdom of Prussia makes an appropriate time to review its vital statistics. The last quarter of a century is marked by a decline both in birth and death rates, and by a relative increase of city population compared with that of the country districts. The birth rate was at its maximum (42.8 per 1,000 of the population), in 1875, and has nearly reached the minimum of 35.3 which prevailed in the year after the Franco-Prussian War (1871). The death rate has also fallen from 30 to 23 per 1,000. The population of the towns has increased about 75%, and that of the country about 15% in twenty-five years.

The infant mortality is greater in the towns, and also greater in the east than in the more civilized west. The mortality of male adults is greater in the coal and iron districts. The birth rate is higher in the country. There is no evidence of city degeneration, "though in many places there are physical differences founded on occupation in youths due for military service, which are against the towns."

The more highly educated, though not physically inferior, do not show that corporeal superiority which might be expected from their more favorable circumstances.

Increase of Cancer in Germany.[40]

The present increase of cancer in Germany, if continued at the same rate to the end of the century, will give a death rate of 22 per 10,000, which is the present consumption mortality of Germany, and if by that time the death rate from consumption shall be reduced to 5 per 10,000, the destructiveness of the two diseases will have been reversed. There is, however, no reason for supposing any connection between the two diseases, since the people of Saxony and Baden, while sharing in the increase of cancer, show no decrease in consumption.

In general, in Prussia, the cancer mortality in

[36] Ges. Ingenieur, July 31, 1899, p. 23.

the towns is twice as great as it is in the country, 7.9 and 3.8, and the mortality from this cause in large cities is greater than that of small ones. Some places, like Stralsund and Schleswig, have twice as many deaths from this cause as occur in Treves and Coblentz.

The Death Rate of Buenos Ayres.

Dr. Carrasco[41] presents some very striking figures, showing a very marked diminution in the death rate of Buenos Ayres since the introduction of pure water and a sewer system. The general death rate fell from 30 per 1,000 in 1890 to 17.1 in 1899, and the typhoid death rate fell from 1.15 to .14 in the same period.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

MEETING of January 15, 1901, the president, DR. ALFRED WORCESTER, in the chair.

DR. F. W. TAYLOR read, by invitation, a paper entitled

PATHOLOGY OF THE NEWBORN.[1]

DR. HIGGINS: Recently I saw in a report of a very interesting case of hemophilia,[2] from the autopsy of which were isolated several forms of bacteria, from which various interesting conclusions were deduced, among others, that hemophilia neonatorum is the result of infection — a view that might throw much light on such cases.

DR. ENGELMANN: Some time ago I saw with Dr. Williams, of Johns Hopkins Hospital, a case of delayed respiration, in which a most vigorous spanking worked to perfection. I would like to call attention to the value of a smooth square-ended catheter to free the throat of newborn infants from mucus. When I was studying in Berlin it was the custom that all students should be equipped with such a catheter. This is certainly more advantageous than blowing air into the lungs.

DR. J. G. BLAKE: I would like to say a word of warning as to heroic treatment being applied to cases of delayed respiration. I remember a case in which hot air, combined with very vigorous friction, resulted in most of the cuticle being rubbed off the child. Spanking of course does no harm generally; but the possibility of black and blue spots being left should be borne in mind, as they are something that parents object to most heartily, forgetting they resulted from efforts to bring the child to life. A man who has never seen a case of hemorrhage from the umbilicus can have no conception of how persistent a thing it may be, in spite of every kind of treatment. I would suggest as a possible substitute for the catheter used to aspirate mucus from the trachea, the use of the little suction syringe used to remove tenacious mucus from the cervix.

DR. C. M. GREEN: The treatment of asphyxia of the newborn should depend upon the degree of asphyxia. If the child is livid, it will generally respond to cutaneous stimulation, or to the shock of the alternate hot and cold plunge, after the trachea has been freed from mucus. But when in pallid asphyxia the reflexes are lost, and the hot and cold plunge is not only useless, but injurious. In pallid asphyxia the pulse is feeble and rapid, and the child is best treated, in my opinion, by immersion in hot water, and by direct mouth to mouth insufflation of air. Sometimes a few drops of brandy subcutaneously are advisable. The French have a tracheal catheter of silver, by means of which the trachea is freed from mucus by the help of a rubber bulb. But in my experience, the mucus and other inspired fluids are best removed by suspending the child by the feet. It has always seemed to me that Schultze's method of resuscitation exposed the feeble child to too great loss of heat.

DR. BLAKE: I should like to ask Dr. Taylor whether in his series there were any cases of apparently healthy, naturally born children dying suddenly without any cause that could be found out. I remember such a case where the autopsy showed absolutely nothing.

DR. W. E. BOARDMAN: I remember a similar case, in which the healthy child of a multipara, born after a simple natural labor, died on the second day, with no apparent cause.

DR. G. J. ENGELMANN: I have got the best results by keeping the child in hot water with the heart exposed, and then from time to time pouring cold water over the heart and head, so as to get the mechanical as well as the thermal shock.

DR. TAYLOR: In regard to melena I think that the general feeling now is that it is of infectious origin. Suspension, as far as I have tried it, has proved very successful. It should, however, be prolonged enough to allow the child to take a number of breaths. I agree with Dr. Green, that keeping up the vital heat is most important in the pallid children. I keep them in warm water, taking them out only occasionally to sprinkle them with cold water.

DR. H. T. SWAIN, by invitation, presented a paper entitled

A CASE OF CHIN LEFT POSTERIOR.[3]

DR. TAYLOR: I should like to ask, as Dr. Swain has spoken of the child's head being retracted some months after birth, whether there was any mechanical cause in the formation of the child to account for the presentation.

DR. SWAIN: Apparently the retraction was merely the result of muscular strain.

DR. J. B. SWIFT: In the 1 case of face that I have seen, I managed to change it to an occiput anterior by grasping it and bringing it down. I have been surprised to see in a recent article in

[41] Boletin Dem. Argentino, vol. 1, August, 1899, p. 31.

[1] See page 347 of the Journal.

[2] Nicholson, American Journal Medical Sciences, October, 1899.

[3] See page 352 of the Journal.

the *New York Medical Journal* that it is an easy thing under deem anesthesia to push the head back to correct such malpositions.

DR. C. M. GREEN: I think that would depend on the amount of uterine retraction. If the uterus is not too dry and retracted, the head may be pushed up and flexed, or internal podalic version may be performed. I have succeeded in doing this in 1 of the 4 cases of low face presentation I have seen. But this would be hazardous, if not impossible, if the uterus is markedly retracted. It is difficult to believe that a fully extended head in the pelvis can be flexed, unless the head is relatively small. But Malcolm McLean reports 2 cases in which he has successfully delivered in this way. If the low face presents the chin anteriorly, delivery by forceps is not difficult. But when the chin is posterior, and the head cannot be flexed nor be pushed up, forceps may secure an anterior rotation of the chin. Failing this, nothing remains but symphyseotomy or craniotomy.

DR. F. A. HIGGINS: I have seen but 1 face case, and that took care of itself. I think such cases would often do well under the relaxation that comes with deep anesthesia. I have often noticed the ease — too much so, sometimes — with which, under anesthesia, one can reflex a partially extended occiput posterior, which was apparently fixed, without ether.

DR. BOARDMAN: The secret of success in the writer's case seems to lie in the fact that the uterus was not retracted. Experience has shown that such cases are generally fatal with a fully retracted uterus, even under deep anesthesia. In the 2 face cases that I have seen, the labor took care of itself in one, and in the other I resorted to version at an early stage.

DR. ALFRED WORCESTER: I agree with the reader that the fortunate issue depends on whether the uterus be fully retracted or not. In this case it had also much to do with the ready skill and discretion of the operator in following nature's lead. I was glad also of the reluctance with which he spoke of doing perforation. A few years ago any young operator would have felt justified in perforating in such a case. Consideration for the unborn child is certainly increasing. I am therefore much surprised that Dr. Green should not have included Cæsarean section among the possible alternatives. To me in such a case, with the uterus in tonic contraction, Cæsarean section offers much less risk to the mother than does version, not to speak of the much greater safety of the child.

DR. BLAKE: I was going to bring up that same question myself. My feeling is that symphyseotomy is going to be relegated to obscurity, now that the perfected Cæsarean section is becoming an operation of such safety. I have never got over my old feeling that the danger, by a symphyseotomy, of making a woman a partial cripple for life is to be avoided if possible.

DR. GREEN: I am by no means an opponent of Cæsarean section, or an advocate of symphyseotomy. Both operations have their proper indications, and I think symphyseotomy should be employed only in those cases in which the woman is either septic or in a poor condition for an abdominal operation. High faces can usually be dealt with by version, or, after flexion of the head, by high forceps. But when the head is in the pelvis, and extended to a face, chin posterior, when the uterus is in such a condition of retraction that the head cannot be pushed up and version performed, or when the head is so impacted that anterior rotation of the chin cannot be accomplished with the hand or forceps, I do not believe that the mother is in any condition for a safe Cæsarean operation. Moreover, in such cases the child would generally be dead, and might as well be delivered by craniotomy; but if the child is alive, symphyseotomy would then be preferable to Cæsarean section, in my opinion, as involving less risk to the mother. The results of Cæsarean section are not good when the patient has been long in labor, no matter how skilful and clean the operation.

DR. WORCESTER: I do not yet understand how Dr. Green can exclude Cæsarean section from the alternatives. I maintain that if symphyseotomy could be done, Cæsarean section should be. As the head is wedge-shaped when in the pelvis, I cannot imagine any very great difficulty in delivering it by Cæsarean section, either by pulling from above or pushing from below. I believe the dangers of a clean Cæsarean section are much less than those of a possible rupture, and certainly less than those of a symphyseotomy.

Recent Literature.

A Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By various writers. A new edition, completely revised and rewritten. Edited by ALBERT H. BUCK, M.D. Volume I. Illustrated. Pp. 799. New York: William Wood & Co. 1900.

A new wholly revised and rewritten edition of this notable work is appearing under the editorship of Dr. Albert H. Buck. The first volume gives promise of a complete cyclopedia of medicine, which will be of very great value, not only as a work of reference, but also as a source of original information on many subjects. The individual articles are written by experts, who have evidently been carefully selected for their special tasks. The success of a comprehensive book of this character depends in great measure upon the ability of its editor to enlist equally competent men in the preparation of articles. In this, Dr. Buck appears to have been peculiarly fortunate, judging from the names which appear as department advisers and also as individual contributors.

This first volume includes A and a part of B. The illustrations are abundant and helpful, and when necessary for clearness are usually, though, we regret to say, not always, printed on special

paper. The microphotographs of bacteria, for example, are excellent, and admirably reproduced. The type, though rather small, is perfectly clear, and the subjects are conveniently placed in heavy type at the head of each page. In general the book fulfils all the requirements of an encyclopedia, and will unquestionably fill a place as a reliable epitome of the rapidly growing and diversified knowledge now included under the head of medical science. We shall look forward with interest to the later volumes, which, it is hoped, may appear at reasonably short intervals.

Forty Years in the Medical Profession: 1858–1898. By JOHN JANVIER BLACK, M.D., Member of the College of Physicians of Philadelphia; Member of the Delaware State Medical Society, etc. Philadelphia: J. B. Lippincott Co. 1900.

This is a volume of 498 pages, covering the experience of a physician who has observed much during an active practice of forty years. The book abounds in reminiscences of well known men of the past fifty years, and many facts are related in entertaining style of their sayings and doings. The state of medical knowledge forty years ago is depicted from the point of view of an eye-witness, and finally a phenomenal amount of information is given on foods, beverages and fruits. It is natural that most of the text is a matter of common knowledge, nevertheless no one could read it from cover to cover without gleaning many facts which he did not know before. The book is rather too long, but most of it is entertaining and instructive, and it permits, fortunately, of judicious skipping. It is sufficiently well bound, and is printed in excellent clear type.

Obstetric and Gynecologic Nursing. By E. P. DAVIS, A.M., M.D., Professor of Obstetrics in Jefferson Medical College and Philadelphia Polyclinic. Pp. 402, fully illustrated. Philadelphia and London: W. B. Saunders & Co. 1901.

This book, intended as a guide and textbook for the obstetric and gynecologic nurse, is an attractive volume with respect to its size, style and contents. The text is written in a plain and concise manner with clear and simple directions for the nurse's conduct, while the book does not abound in a large amount of material which the nurse can not and should not be expected to know. The obstetrical nurse of today should and does have special technical training and skill, but this training when best given is confined to the duties of the nurse herself, with respect to the care of the patient, her assistance of the attending physician, and the care of such emergencies as may arise in his absence. This the author evidently kept in mind throughout and has attained to a marked degree in his work; consequently the book is not an abbreviation of an obstetric textbook, but the best book on obstetric and gynecologic nursing that has come to our notice.

The book is divided into two parts; the first part, comprising 240 pages, is devoted to obstetric nursing and care of the young infant, and part two, of about 120 pages, is confined to gynecological nursing. There is also an excellent appendix, of about 30 pages, devoted to dietary and to the preparation and sterilization of surgical supplies.

Throughout this book the author has wisely limited his descriptions to directions for the nurse's work, with no attempt to indicate reasons or details for operative procedure. Much good advice is offered the nurse against the assumption of too much responsibility in certain conditions, such as the examination for lacerations after delivery, and the taking of unwritten orders from the physician in the treatment of cases after abdominal section.

Manual of the Diseases of Children. By JOHN MADISON TAYLOR, A.M., M.D., and WILLIAM H. WELLS, M.D. Second edition, thoroughly revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1901.

The entire work has been thoroughly rewritten and much new material added. In the preface to the first edition the authors stated that they did not claim that their book was a treatise on the maladies of childhood, but they presented it as a practical working manual for the student and practitioner. The first edition, however, was well worthy the title of "treatise," which the authors so modestly disclaim. The second edition, a volume of more than 800 finely printed pages, deserves this title even more, and is far more complete than many books on the diseases of children with more ambitious titles.

The arrangement of the work, is on the whole, fairly satisfactory, although diseases and symptoms are, to a certain extent, confused. Appendicitis is strangely enough classified under "Diseases of the Peritoneum." Tuberculosis of the peritoneum and tubercular meningitis are not classified with tuberculosis as they should be.

It would seem better to have taken up membraneous croup, that is, laryngeal diphtheria, with diphtheria instead of with diseases of the respiratory organs. To take it up with them only perpetuates the confusion of former years. Laryngismus stridulus belongs with the diseases of the nervous system rather than with those of the respiratory organs. We can see the possible explanation for placing exophthalmic goitre among the diseases of the nervous system, but hardly any for placing myxedema there also. Tetanus belongs among the "Specific Infectious Diseases," rather than among those of the nervous system. Other exceptions might also be taken to the arrangement. Perhaps more have been taken than seem advisable in a review. We feel, however, that much harm may result, especially to students, from getting a wrong point of view in the beginning. The relative amount of space given to different diseases is, in many cases, also peculiar, for example, diphtheria has more than thirty pages, and general tuberculosis less than one.

The pathology of disease has probably received

as much attention as the limited space warranted. The sections devoted to symptomatology, however, are sketchy and far from clear. Those devoted to diagnosis are incomplete and unsatisfactory. The newer and more accurate methods of diagnosis have hardly been given due prominence. Much space has been given to treatment, which is very complete. There is a tendency here, however, to glittering generalities and to long lists of drugs "which may be used." We fear that the student may often be confused, and feel that less but more definite treatment would be more useful to him.

The chapter on the feeding and food of infants and children is one of the best in the book. It is well up to date and is written in a very practical manner. Much attention is devoted to the home modification of milk while laboratory feeding is not neglected. This chapter cannot fail to be most useful to the practitioner. The chapter on the diseases of the digestive organs is also good.

We cannot, however, agree with the classification. The great importance of diet rather than of drugs in the treatment of these diseases is duly emphasized. The standard of the rest of the book is uniform, but on the whole is not quite up to that of the chapters mentioned. The authors' point of view in many instances seems that of adult medicine rather than that of pediatrics. The chapters on the ear and skin are especially commendable.

As a whole, however, the work is very satisfactory. It is well worthy the careful study of both student and practitioner, and cannot fail to prove of great value to both. We do not hesitate to recommend it.

The Essentials of Practical Bacteriology. An Elementary Laboratory Book for Students and Practitioners. By H. J. CURTIS, B.S. and M.D. (Lond.), F.R.C.S., Late Surgical Registrar, University College Hospital; formerly Assistant to the Professor of Pathology, University College, London. London, New York and Bombay: Longmans, Green & Co. 1900.

This book represents one more addition to the growing list of laboratory manuals for students of bacteriology. It deals not only with the bacteria proper, but includes some consideration of the moulds, fermentation, malaria, psorospermosis and cancer. The published work of Plimmer on cancer is extensively quoted and his results are apparently accepted by the author. The text of the book seems to fairly well represent the main points in our knowledge of bacteria and of the other subjects with which the book deals. This is to be expected, because with so many other books on bacteriology available for reference it would be gross carelessness for an author to make many erroneous statements. As compared with these others, this book presents no special improvement. It surely does not fill any general and widely felt want. The illustrations are numerous. Practically all of the figures of bacteria are made from diagrammatic drawings. They are much inferior to good photomicrographs.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 11, 1901

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

PLAGUE IN SOUTH AFRICA.

AT the beginning of the appearance of plague at Cape Town grave apprehensions were at once felt lest the disease should prove difficult to eradicate. This fear has proved in great measure well founded, owing to the peculiarly disadvantageous conditions under which the health authorities are obliged to work, chiefly because of the ignorance and prejudice of a large portion of the population.

It is said that upwards of twenty thousand people from the seat of war have sought refuge in Cape Town, which is none too well able to care for its own population. No proper provision could, under the circumstances, be made for these refugees, among whom were women and children, with the natural result that they became a source for the inception and spread of disease. As regards the sanitation of Cape Town, a correspondent in a daily paper writes, perhaps rather extravagantly, that it is one of the dirtiest, if not the dirtiest city in the world, and that the system for the disposal of the city's refuse is the same as that in vogue in Jerusalem two thousand years ago. However this may be, it is safe to assume that so mixed a population as that of Cape Town, of which whole classes have their own peculiar superstitions, must be a constant menace to the health of the community at large. The Malays appear to be the most difficult class to control, owing to the practical impossibility of forcing them to abide by the ordinary laws of burial. These Malays live in the midst of the city, which is now densely populated, so that the tracing of a disease like plague in its early stages becomes a matter of very great difficulty. It is said, furthermore, that the peculiar religious doctrines of these people prevent the employment of a regular undertaker, custom demanding that, regardless of the cause of death, the corpse must be borne through the streets in an open coffin to the grave, where it is left exposed

over one night. The friends of the deceased visit the cemetery under these conditions and deposit near the grave various edibles. This exceedingly unhygienic custom has been found difficult to suppress, and a considerable conflict with the authorities has resulted. The Kaffirs are also a problem. They live in the most squalid fashion, and naturally without an idea as to cleanliness. The government has attempted to collect them in one locality, thereby permitting a more perfect supervision than would be possible were they allowed to live in places of their own choosing.

In such a population it is easy to see how fertile a field is provided for the spread of plague, and although the disease may hardly as yet be said to have reached grave epidemic proportions, nevertheless the continued reports of fresh cases, ten for example on April 8th, and four of these among Europeans, is not altogether reassuring. Hope is expressed that certain gales from the southeast, which are ordinarily prevalent at this period of the year, may lighten the situation by clearing the atmosphere and washing away filth. It is, however, sufficiently apparent that an ultimate eradication of this disease or any other of a similar sort, must come from a complete regulation of the hygiene of the city, no douht in this case difficult of accomplishment, but certainly possible, if sufficiently active measures be taken, and sufficiently stringent laws enacted.

REPORT OF BROOKLINE, MASS., BOARD OF HEALTH.

Whether inspired by the example of larger and more thickly populated neighboring cities, or aroused by a consciousness of their own immediate needs, it is evident that suburban towns are every year making decided progress in municipal sanitation. Good work has been done in many localities as communities have awakened to their responsibilities in dealing with those problems of disease which come under public jurisdiction. We have before us the Report of the Board of Health of the town of Brookline, Mass. It contains the usual facts and figures regarding mortality and disease and alludes to various improvements in the work of the Board during the year. Owing to the prevalence of diphtheria last fall and during the early winter an added building for an isolation hospital was supplied by the erection of a somewhat hastily built structure which, however, answered its purpose sufficiently well. Of the 161 patients admitted to the hospital during 1900, 137 had diphtheria and 14 scarlet fever. Of the 137 diphtheria patients all except 4 recovered (a mortality of less than 3%), and of the 14 scarlet fever patients, the whole number recovered. To the use of antitoxin, provided by the State Board of Health, the very small death rate in the diphtheria hospital is in large part due.

Disinfection after a death from consumption is required, and the free bacteriological examinations to determine an early diagnosis of diphtheria and typhoid fever have been more extensively taken advantage of than in preceding years. Of very great importance has been the establishment of a laboratory under the charge of a skilled bacteriologist. Systematic investigations have been undertaken and carried out in this laboratory which are not only a credit to the town but also a distinct contribution to medical knowledge. The regular work has been the examination of cultures from suspected cases of diphtheria; the examination of sputum for the early detection of cases of pulmonary tuberculosis, and the application of the Widal test in suspected typhoid fever. Some interesting observations on the presence of diphtheria bacilli in supposed healthy persons were made, which should be of value in estimating the danger of infection. Of this investigation the Report states:

> Cultures from 1369 *healthy* persons were examined. When a school child has been taken sick with diphtheria, the school inspectors have made cultures from those children sitting adjacent to the child, or from all the children in the same room. In this way, 1154 cultures have been made and 43 healthy children with the bacilli in their throats or noses were discovered. In 18 of these the bacilli were very few in number and present only on one day, as the cultures which were made on the day following and subsequently were negative. It is hard to explain these cases which appear to be so slightly and transiently infected. It seems probable that they are not a great source of danger.
>
> Of the 25 cases which were positive on more than one day, 4 were found by inoculation tests to be virulent, 12 were non-virulent, and in 9 the virulence was not tested. Very few of the 1154 school children had been much exposed. In many cases the cultures were made as a precautionary measure where the exposure was only suspected. This explains the occurrence of so few positive cases showing virulence.
>
> In marked contrast to the school cases were the results of examinations of cultures from the healthy members of families where one or more persons had diphtheria. Cultures from 218 persons were examined, among whom 39 (18 per cent) were positive. The bacilli from healthy persons who had been exposed were always found to be virulent when tested, and were therefore capable of transmitting the disease to others.
>
> With very few exceptions, none of these healthy persons with virulent bacilli developed symptoms of diphtheria; many of them doubtless would have done so had they not received a protective dose of antitoxin. The antitoxin prevents, for a few weeks at least, the development of serious symptoms in the individual so protected, and is, therefore, of great benefit, but it does not prevent the germs multiplying in the throat and nose, and so of being transmitted to others. As no symptoms develop after antitoxin is given which would enable a physician to recognize a

case as dangerous, it is only possible to discover the infected throats by means of cultures. Such undiscovered cases may go about spreading the disease, and may infect the rooms which have been disinfected by the Board on the removal of the case to the hospital.

This sort of work is worthy of emulation everywhere and it is in general gratifying to observe that really scientific methods are being more and more systematically introduced in Board of Health laboratories to the evident benefit of the communities in which they are located.

"AMERICAN MEDICINE," A NEW MEDICAL JOURNAL.

THE first number of a new weekly medical journal, advertised for several months, appeared April 6th, with the title "American Medicine." It adds another to the already overcrowded list of such journals, but its editor, Dr. George M. Gould, and its owners are no doubt inspired by the perfectly legitimate ambition of finding room at the top, an ambition which has led to the success of many far more venturesome efforts than this.

In form and general arrangement of contents the new journal is very similar to the *Philadelphia Medical Journal*, of which Dr. Gould was formerly the editor. Original articles are relegated to the latter part of each issue, with editorial comments and items of general medical interest at the beginning. A department of therapeutics has been introduced, and under the rather unnecessarily comprehensive heading, "The World's Latest Literature," is given an epitome of current medical writing as found in certain of the better known and not strictly technical journals. This latter method of disseminating knowledge was introduced into American weekly journalism by Dr. Gould, and is certainly to be regarded as of value, if well done. That it is often very poorly done is perhaps unavoidable, but none the less unfortunate.

The appearance of this first number is gratifying to a lover of good printing; its typographical errors are few in consideration of the fact that this is its first issue, and the material offered to readers is varied and nutritious. The promise of short articles, as made in the prospectus seems doubtful of fulfilment, however, when we note that five of the original papers are of the continued variety. There is considerable editorial comment on the need of independent journalism to which we, in general, most willingly subscribe. We confess, on the other hand, to a feeling of regret that the editor has seen fit to resort to the paralled column method of enforcing his ideas even in so small a matter as in giving advice to subscribers to medical journals. We had hoped that argument put in this form had its place only in political controversy.

A SO-CALLED VICTORY FOR CHRISTIAN SCIENCE.

UNDER the heading "Victory for Christian Science," a daily paper cites a case occurring in Milwaukee in which two Christian Scientists were convicted in a police court of practising medicine without a license. The case was appealed and the judge of the higher court is reported to have ruled that, inasmuch as there never had been any testimony that the defendants had pretended or attempted to use medicine, they could not be held liable, the question at issue being whether the defendants did or did not practise medicine. We can hardly believe that the ruling is correctly reported; if it is we are at a loss to conceive what is legally meant in Milwaukee by the phrase, "practice of medicine." Certainly no liberal-minded or well-informed person imagines nowadays that the practice of medicine means solely the employment of drugs. We should, on the contrary, suppose that the definition as ordinarily interpreted signifies merely the treatment of disease by any means physical or otherwise. A large part of medical treatment has no relation to the use of medicine a fact which the courts ought to know. We have no knowledge of the special case in which the above ruling was made, nor do we wish to express here an opinion as to the advisability of prosecution in such cases in general, but that any person should be freed of responsibility and exempt from processes of law relating to medical practice on the ground that he does not employ medicine in his treatment is a dodging of the real question at issue capable of most serious misinterpretation. If the courts are to maintain that a person may treat the sick without let or hindrance provided only he abstain from giving medicine of what possible significance is a medical practice act?

MEDICAL NOTES.

A PROPOSED ALLIANCE OF AMERICAN COUNTRIES TO COMBAT YELLOW FEVER.—At the recent meeting of the International Medical Association held in Havana the proposition was made to organize a committee of the various American countries to investigate the possibility of establishing a uniform system of quarantine regulations and systematic co-operation for removing the sources and suppressing the causes of yellow fever. A convention is to meet in Havana next February. The invitation to the United States to participate in this convention is now under consideration by Dr. Wyman of the marine hospital service.

YELLOW FEVER IN THE PHILIPPINES.—Dr. F. A. Meacham, president of the Board of Health at Manila, calls attention to a statement in our

issue of December 27, 1900, regarding the presence of yellow fever in the Philippine Islands. He writes: "There have been no cases of yellow fever in the Philippines during the year 1900, and from all obtainable information this disease has never gained an entrance to the Archipelago."

Plague in San Francisco. — Official reports show that a certain amount of plague is endemic in San Francisco. The cases have been comparatively few in number, but of a virulent character. The disease has been confined almost exclusively to the Chinese, but for several years has not increased to a degree to cause alarm.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 10, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 59, scarlatina 33, measles 89, typhoid fever 8.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending April 6th was 211, as against 276 the corresponding week last year, showing a decrease of 65 deaths, and making the death rate for the week 19.6. The deaths from consumption were 32, pneumonia 31, whooping cough 1, heart disease 19, bronchitis 7, marasmus 3. There were 11 deaths from violent causes. The number of children who died under one year was 30; under five years 52. Persons more than sixty years 44; deaths in public institutions 61.

Typhoid Fever in New Haven, Conn. — Within the last few days upwards of 150 cases of typhoid fever have developed in one of the better residence quarters of New Haven. An investigation by the Health Board is said to have shown the cause to be the pollution of a pond which furnishes the water supply for the western part of the city. Infected matter from 3 cases of the disease in the family of a farmer living near the pond was washed into it by the recent rains.

NEW YORK.

Vindication of North Brother Island Hospital. — Robert Martin, a merchant who was recently a smallpox patient in the hospital for contagious diseases on North Brother Island, having published in the newspapers sensational charges as to the existence of gross abuses in that institution, the commissioners of the Board of Health immediately invited representatives of the principal papers to make a visit to the island in company with officials of the department. Had the abuses described really existed there would have been no time to correct them, and the party of visitors came away entirely satisfied that the management of the hospital was efficient and that everything possible was being done for the welfare and comfort of the patients.

Semi-centennial of Dr. Abraham Jacobi's Graduation in Medicine. — On April 5th Dr. Abraham Jacobi celebrated the semi-centennial of his graduation in medicine at the New York Academy of Medicine, having been graduated from the University of Bonn in 1851. On this occasion Dr. Jacobi was himself the host, and entertained a number of the prominent physicians of the city. In a paper on some of his reminiscences he spoke particularly of the German textbooks of fifty years ago, a collection of which he has presented to the library of the academy.

Demonstration of a Mechanical Device to Facilitate Hearing. — Recently Mr. Miller Reese Hutchison gave before the Section on Otology of the Academy of Medicine a demonstration of his telephonic device for enabling the deaf (even deaf mutes) to hear, which excited much interest. He explained that while he did not claim anything curative for his invention, which was simply a mechanical contrivance to facilitate hearing, at the same time he had observed in a considerable number of cases more or less improvement.

Enforcing the Law Regarding Expectoration. — On April 1st the Board of Health began a rigorous crusade against persons expectorating on the floors of street cars and ferry boats. Members of the sanitary police force were sent out in all the boroughs, in citizen's clothes, to watch for offenders against the ordinance forbidding the practice, and a large number were arrested.

Enlargement of St. Mary's Free Hospital. — The trustees of St. Mary's Free Hospital for Children, on West 34th Street, have purchased two city lots on 35th Street, adjoining the buildings, and will erect on the property an addition to the hospital.

A Centenarian. — Louis Voilland, a native of France, who after coming to America was for some time in the service of Madame Jumel, the widow of Aaron Burr, died on April 4th at Mamaroneck, Westchester County, at the age of 103.

Bequest to a Hospital. — Among the charitable bequests of Mrs. Katharine D. Callahan, of New York, who died last month, is $5,000 to St. Francis Hospital, to be devoted to the establishment of the "Rigney-Callahan" ward.

Death after Removal of Stomach. — The patient whose stomach Dr. George R. Fowler removed at the German Hospital in Brooklyn died April 2nd, five days after the operation.

MALARIA IN RELATION TO ENGINEERING AND AGRICULTURE.

PROF. A. CELLI has contributed to the *Journal of the Sanitary Institute*, January 1901, page 617, an extremely valuable and interesting article upon the Relation of Malaria to Engineering and Agriculture, from which the following extracts are taken:

It is therefore now beyond question that a malarial human being, that is, one who has the specific parasites in his blood, is the first source of infection. The anopheles mosquito, which sucks that blood, is the other source of infection, and also the vehicle that carries the germ through the air, and the means of inoculation. It is further certain that these gnats live in humid places at various altitudes, in Italy from 0 to 1,300 metres. But for the local origin of an epidemic, besides a malarial human being and anopheles mosquitoes, there is required a suitable temperature (from 20° to 25° C.), that is, the opportune season, from which fact malaria in old times was also called "seasonal fever."

In order to live on the surface of the earth all gnats require water through the whole period of their aquatic existence, that is to say, in their larval and nymphal stages. As Tommasi-Crudeli had already shown, the soil may be of any nature and constitution, provided it has water on the surface; the water may also be contained in reservoirs outside the earth. Water is therefore the sole and true condition that is indispensable for the development of mosquitoes, and therefore of malaria, in every place where that disease is prevalent.

Briefly summing up the results of very numerous observations it may be stated as indubitable that:

(1) The larvæ of anopheles live in any water, clean or foul, clear or turbid, acid or alkaline, and ferruginous. They do not live in water (1) containing salt (salt marshes, sea water, and mixtures of that with fresh water in the proportion of two to one); (2) very strong sulphur waters; (3) water that is putrid from the putrefaction of animals or textile plants. They avoid water (*a*) in which there is any movement (currents, ripplings caused by even light winds such as sea breezes, mechanical disturbance as by the passage of boats); (*b*) without vegetation of aquatic plants, of which they prefer the filamentous species which do not occupy the whole free surface of the water where they rise to breathe.

(2) The aerial anopheles are little domestic animals which live in and around houses. It is on this account that malaria is so often epidemic, that is to say, a disease which is contracted for the most part in the interior of dwellings, or in their vicinity. They bite in the evening and at night, and from olden times therefore these have been looked upon as the most dangerous hours for the contraction of fevers. The insects are carried to a distance, not only by the wind, which they dread because they are beaten down by it, but passively, that is to say, on man, on his belongings (grass, hay, wood, beasts), and on his means of locomotion (carts, coaches, railway carriages, etc.).

From these facts, which are now thoroughly established, are deducible several corollaries useful in practice for engineers and agriculturists.

(1) *Corollaries for hydraulic engineers.* — In the first place, certain prejudices that have for a long time held sway in the schools have been definitively removed. For instance, it can no longer be maintained that a puddle or lake is improved by the water level being kept constant. On the contrary, if the waters are still and — as happens in the neighborhood of the edges — there grows an aquatic vegetation, there the larvæ of the anopheles gnats mostly make their nests.

Another prejudice, already combated by Tommasi-Crudeli and now definitively buried, is that putrid waters and the emanations therefrom are causes of malarial fevers, whereas on the contrary, it has been seen that the specific gnats do not live in stinking waters.

Another prejudice which is already crumbling away, although the Paris Academy of Medicine not long ago attempted to revive it, is that waters which are brackish owing to a mixture of fresh water with sea water, and salt marshes along the sea-coast are very unwholesome.

Having thus briefly seen which are the gnat-breeding, and therefore the malaria-breeding waters, I pass on to indicate the new criteria with which engineers who have to carry out hydraulic improvements designed to free districts from malaria should be acquainted.

It is known that these improvements can be secured by means of, (*a*) Natural drying by large canals with a high-level water course; (*b*) mechanical drying by means of pumping engines; (*c*) earth embankments; (*d*) drainage. This last method may be sufficient of itself or may be complementary to those previously mentioned.

(2) *Corollaries for sanitary engineers.* — The house in malarial regions may, as has been said, be the point of greatest danger from fevers, while on the other hand, if properly built and equipped, it may be the safest place. Formerly, in every malarial district, it used to be required (and as far as possible it ought still to be required) that the house should be built in the highest and dryest situation possible; but this is not sufficient, for the gnats, directly or passively, will get up to it.

Other structural conditions are today more necessary, whenever a house has to be built in a malarial place. Above all there should never be a dark or badly lighted part in the house. If there is such a part, as for example, in the cellars, under the stairs, in the latrines, gnats will certainly hide there.

The walls of the rooms must be white, so that every gnat that rests on them may at once be seen. From the bedrooms it will be necessary to remove pictures, curtains, and such articles of furniture as shelter gnats. If by chance one is heard in the night, a powder should be burnt which at any rate will stupefy it, so that afterwards in the morning it can be looked for and killed. Care should be taken that there are no holes in the floor, or if there be any, that they should be closed.

It is advisable to avoid having trees about the houses, as in the daytime the mosquitoes hide there, which in the evening try to make their way into the houses, especially into rooms where there is a light burning.

Finally, any kind of habitation in a malarious place, even to temporary sheds that can be taken down and straw huts, should be protected against the invasion of mosquitoes. The walls should be of netting, or be made somehow impermeable to those insects, and in every case a cage with an outer and an inner door of metallic netting should protect the entrance.

With such mechanical protection, last year I, for the first time, made it possible for the families of railway servants to pass the whole summer and autumn in the most malarial spots of the Campagna without contracting the fever; and there is no longer any doubt that it is possible to keep a house free from mosquitoes, and therefore from malaria, in the regions most infected by that epidemic disease.

(3) *Corollaries for agriculturists.* — It must first of all be understood that any turning of the soil cannot by itself be a cause of malaria, as was believed when it was supposed that the germs of this infection lived in the ground. Thus the temporary irrigations of dry cultures, as maize, meadows, fields, pot-herbs, oranges, lemons, etc., cannot be a cause of malaria, provided the water reaches the soil in no greater quantity than it does in a shower of rain, and the canals by which it flows in or out are not of such a character as to allow it to become stagnant.

On the other hand, marsh lands or irriguous fields which are kept in a state of prolonged submersion may be a cause of malaria, not by reason of the water which is poured over the fields, and during the fever season is not left there, but by reason of the water which stagnates in the canals round the square patches of meadow.

My own experiments and those of my fellow-workers in various parts of Italy, have shown that ricefields, whether the water in them be stagnant, running, or intermittent, are always a favorite nidus of the anopheles larvæ.

Does the culture of shrubs, and in general of trees, favor the propagation of malaria, or does it not? It can no longer be maintained that, at any rate among us, there exist culicifuge trees, and that of this nature, as the Paris Academy of Medicine persists in believing, are the pine and the eucalyptus. These and our other trees are, on the contrary, shelters for the insects of the air, and therefore in the neighborhood of houses, as in our railway cottages, they rather entail a danger of malaria. On the other hand, some herbaceous plants, chiefly the closed flowers of the chrysanthemums of Dalmatia and Montenegro, from which are prepared the so-called insecticide powders, are effectual in killing the larvæ in water and the mosquitoes in the air. If it were possible to cultivate these plants on a large scale, it might be possible also to contrive that the malarial place itself should produce as much as would suffice to free it from the mosquitoes by which it is infected.

Lastly, *intensive cultivation* is notoriously that which best reconciles hygiene with rural economy. And how this is so we are now in a position to explain. Dry soil, temporary irrigations, strict conservancy of canals, even the foul liquids of natural manures, are so many conditions unfavorable to the life of the larvæ of the fever-breeding mosquitoes. And thus it is understood how, wherever it has been possible to secure all this, intensive cultivation has brought economical prosperity and health to wretched and inhospitable waste lands.

(4) *Brief notions of prophylaxis for laborers in malarious places.* — It is altogether to the interests of engineers and agriculturists to safeguard the health of him who works for them much more than he does for himself. It is well, therefore, that they should know how they can and ought to do this. It is obviously necessary that, in every primary and recurrent case of malarial fever, treatment by means of quinine should be prompt, as complete as possible, and therefore prolonged and gratuitous.

For this purpose he also advises protection of laborer's dwellings by screens, protection of the uncovered parts of the body, and shortening or abolition of night and evening work. He also recommends the administration of euchirim to produce immunity.

"RUDOLF VIRCHOW FUND."

TO THE AMERICAN MEDICAL PROFESSION: — On October 13, 1901, Rudolf Virchow will be eighty years old. When he completed his seventieth year a fund was started in his honor to enable the great master to facilitate scientific research by establishing scholarships, and by encouraging special medical and biological studies. Contributions to that "Rudolf Virchow Fund" were furnished by those in all countries interested in progressive medicine, as a homage to the man whose name is always certain to arouse admiration and enthusiasm.

In Berlin a large committee, containing among others the names of A. Bastian, V. Coler, A. Eulenburg, B. Frænkel, O. Israel, Fr. Kœnig, C. Posner and W. Waldeyer, has been formed to call for contributions which are to be added to the original "Rudolf Virchow Fund" so as to increase its efficiency. The committee expresses the opinion that in no better way, and in none more agreeable to the great leader of modern medicine, can his eightieth birthday be celebrated, and ask for the sympathy and co-operation of all those engaged in the study and practice of scientific medicine all over the globe.

The undersigned have formed a sub-committee for the purpose of making the American profession acquainted with the intentions of the Berlin Committee, and urge their colleagues to participate in honoring the very man who has done more, these fifty years, than any other to make medicine a science, and international.

Subscriptions should be sent to their secretary, who will receipt therefor.

CHARLES A. L. REED,
President of the American Medical Association.

HENRY P. BOWDITCH,
President of the Congress of American Physicians and Surgeons.

WILLIAM H. WELCH,
Johns Hopkins University.

ROBERT F. WEIR,
President of the New York Academy of Medicine.

A. JACOBI, 110 West 34th St., New York,
Secretary.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 30, 1901.

CITIES.	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Newburyport	14,478	3	—	33. 33	—	—	33.33	—
Melrose	12,962	—	—	—	—	—	—	—

Deaths reported 2,939; under five years of age 858; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 664, acute lung diseases 485, consumption 376, diphtheria and croup

83, diarrheal diseases 53, scarlet fever 56, influenza 19, typhoid fever 29, whooping cough 11, measles, 13, cerebro-spinal meningitis 3, smallpox, 11.

From whooping cough, New York, 2, Philadelphia, 3, Baltimore, 1, Pittsburg, 3, Boston, 2, Holyoke, 1. From cerebro-spinal meningitis Boston, Everett and Clinton, 1 each. From scarlet fever, New York, 38, Philadelphia, 8, Boston, 8, Somerville and Brockton, 1 each. From typhoid fever, New York, 11, Philadelphia, 4, Baltimore, 1, Pittsburg, 4, Providence, 3, Boston, and Fall River, 2 each, Chicopee and Newburyport 1 each. From measles, New York, 8, Pittsburg, 2, Boston 2, Cambridge, 1. From smallpox, New York, 10 Pittsburg, 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending March 16th, the death rate was 18.9. Deaths reported, 4,280; acute diseases of the respiratory organs (London), 394, whooping cough 112, diphtheria 66, measles 105, fever, 23, scarlet fever, 30.

The death rates ranged from 13.8, in West Ham, to 28.2, in Liverpool; Birkenhead, 14.9, Birmingham, 22.2, Blackburn, 18.0, Bolton, 14.7, Bradford, 14.9, Brighton, 14.6, Bristol, 21.7, Burnley, 14.3, Cardiff, 18.5, Croydon, 15.1, Derby, 14.7, Gateshead, 19.0, Halifax, 21.5, Huddersfield, 17.3, Hull, 18.9, Leeds, 19.8, Leicester, 15.1, London, 17.6, Manchester, 19.9, Newcastle-on-Tyne, 18.2, Norwich, 18.4, Nottingham, 18.4, Oldham, 24.8, Plymouth, 26.6, Portsmouth, 20.1, Preston, 21.7, Salford, 21.5, Sheffield, 20.7, Sunderland, 29.0, Swansea, 14.6, Wolverhampton, 15.0.

METEOROLOGICAL RECORD.

For the week ending March 30th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

SOCIETY NOTICE.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — A regular meeting will be held at 3 Park Street on Thursday, April 18th, at 7.30 P.M.

Papers: Dr. N. Louise Lawrence, "Tonsillitis"; Dr. Agnes C. Vietor, "The Pathology of Tonsillitis, Illustrated."

Discussion: Dr. Elizabeth C. Keller, "Tonsillitis from the Standpoint of the Surgeon." Dr. Alice G. Bryant, "Tonsillitis from the Standpoint of the Specialist."

AGNES C. VIETOR, M.D., Secretary,
Trinity Court.

LECTURES AT NEW YORK SCHOOL OF CLINICAL MEDICINE. — The New York School of Clinical Medicine offers a series of lectures open to the profession weekly from April 5th to June 7th on varied topics.

THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — The American Gastro-Enterological Association will hold its annual meeting May 1, 1901, at Washington, D. C.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held in Sprague Hall, Medical Library Building, Fenway, on Monday, April 15, 1901, at 8.15 P.M.

Papers: Dr. Robert T. Edes, "Observations on Heart Disease"; Dr. Edward O. Otis, "Health Resorts."

ARTHUR K. STONE, M.D., Secretary,
657 Boylston Street.

AMERICAN ACADEMY OF MEDICINE. — The Twenty-sixth Annual Meeting of the American Academy of Medicine will be held at St. Paul, Minn., June 1, 2 and 3, 1901.

SUFFOLK DISTRICT MEDICAL SOCIETY. — A regular meeting of the Section for Clinical Medicine, Pathology and Hygiene will be held in Sprague Hall, Boston Medical Library Building, No. 8 The Fenway, Wednesday, April 17th, at 8 P.M. DR. S. A. KNOPF of New York will read a paper upon "Municipal Care for Consumptives." Discussion by Dr. J. H. Prior of Buffalo, Drs. F. I. Knight, E. O. Otis and V. Y. Bowditch.

H. F. HEWES, Secretary.

BOOKS AND PAMPHLETS RECEIVED.

Nursing Ethics: For Hospital and Private Use. By Isabel Hampton Robb. Cleveland: J. B. Savage. 1901.

A Text-book of Diseases of the Nose and Throat. By D. Braden Kyle, M.D. Illustrated. Second edition. Philadelphia: W. B. Saunders & Co. 1901.

Repairing the Abdominal Wall in Ventral Hernia: A New Operation. By Carl Beck, M.D., of New York. Illustrated. Reprint. 1900.

An Index of Symptoms. As a clew to Diagnosis. By Ralph Winnington Leftwich, M.D. Second edition. New York: William Wood & Company. 1901.

International Medical Annual. A Year-Book of Treatment and Practitioner's Index. Nineteenth Year. New York and Chicago: E. B. Treat & Co. 1901.

The Medical News Pocket Formulary for 1901. By E. Quin Thornton, M.D. Third edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co. 1901.

Second Annual Report of the State Board of Insanity of the Commonwealth of Massachusetts for the Year Ending September 30, 1900. Boston: Wright & Potter Printing Co. 1901.

The Treatment of Fractures. By Charles Locke Scudder, M.D. Assisted by Frederic J. Cotton, M.D. Second edition, revised. Illustrated. Philadelphia: W. B. Saunders & Co. 1901.

A Compend of Human Physiology. Especially Adapted for the Use of Medical Students. By Albert P. Brubaker, A.M., M.D. Tenth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1901.

Human Placention. An Account of the Changes in the Uterine Mucosa, and in the Attached Fetal Structures, During Pregnancy. By Dr. J. Clarence Webster, B.A., M.D. (Edin.), F.R.C.P.E., F.R.S.E. Illustrated. Chicago: W. T. Keen & Co. 1901.

Retinoscopy (or Shadow Test) in the Determination of Refraction at One Meter Distance, with the Plane Mirror. By James Thorrington, A.M., M.D. Fourth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1901.

Pulmonary Consumption, Pneumonia and Allied Diseases of the Lungs. Their Etiology, Pathology and Treatment, with a Chapter on Physical Diagnosis. By Thomas J. Mays, A.M., M.D. Illustrated. New York: E. B. Treat & Company. 1901.

Introduction to the Differential Diagnosis of the Separate Forms of Gallstone Disease. Based Upon His Own Experience Gained in 433 Laparotomies for Gallstones. By Professor Hans Kehr. Halberstadt. Authorized Translation by William Wotkyns Seymour, A.B Yale, M.D. Harvard. Introduction by Professor Kehr. Philadelphia: P. Blakiston's Son & Co. 1901.

Transactions of the American Dermatological Association, at its Twenty-fourth Annual Meeting held in Washington, D. C., May 1, 2 and 3, 1900. In Connection with the Fifth Triennial Session of the Congress of American Physicians and Surgeons. Official Report of Proceedings by Frank Hugh Montgomery, M.D., Secretary. Chicago: P. F. Pettibone & Co., Printers. 1901.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D. Second edition, revised and largely rewritten. Vol. III. Anesthesia and Surgical Technique. Fractures and Dislocations, and Minor Surgery. Surgery of the Lungs and Pleura and of the Peritoneal Cavity, the Rectum, and Anus. Diseases of the Genito-Urinary Apparatus and of Parturition and of the Puerperium. Diseases of the Eye and Ear and of the Upper Respiratory Tract. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1901.

THE OPINION EVIDENCE OF MEDICAL EXPERTS.[1]

BY JOHN D. MCLAUGHLIN, BOSTON,
Assistant District Attorney.

THERE are few branches of the law, particularly that of evidence, which have more than a general interest for those not of that profession. The subject, however, of expert testimony, and especially that of medical experts, is singular, in that apart from its own intrinsic importance, it excites equal concern in two great professions, the medical and legal. The interests of the physician and the lawyer (as well as of the layman whose property or liberty, when a party, may be intimately involved, or who, as a juryman, may be called to sit in judgment) here converge in a common centre. The discussion which has waged for years, and while present conditions obtain, will wage long hence, and the numerous proposals for reform in the reception of such testimony has been about equally participated in by these several interests. Each from time to time, through the channel of medical journal, legal periodical or the newspaper, is contributing some thought or suggestion to the subject; and I cannot but believe that your society, whose end is the advancement of the science of forensic medicine, regards it, however trite, as one of surpassing importance.

Some months ago, I had the honor to read, before the medical society of a neighboring county, a paper in which I discussed the position of the medical expert as lawyers see him upon the stand today, and said, in passing that the many proposed schemes of reform seemed to me speculative and impractical. In so far, at least, as I may have seemed by that remark to endorse the method which now prevails in England and America, I beg leave to disclaim that opinion.

When the physician testifies as merely an ordinary witness to facts which have come within his observation, he excites no greater interest or attention than that which might attend the testimony of an intelligent witness from any other vocation. His effectiveness, persuasiveness, and claims to belief depend upon the same conditions as do those of any witness. But when testifying to his opinion, based either on facts which he has himself observed, on admitted facts, or upon some hypothesis, expressing the judgment of a scientific man, ready to submit it to the opinion and criticism of the members of his own profession, to the cross-examination of counsel, publicly and to the world, then he frequently evokes an interest which rarely surrounds a witness under any other circumstances. There is, indeed, no phase of evidence which has attracted more attention, which has been the object of more criticism (frequently from bench and bar) or more the subject of proposed reforms than the opinion testimony of medical witnesses as uttered on the witness stand.

[1] Read before the Massachusetts Medico-Legal Society, February 6, 1901.

Of the scope and extent of such criticism, at least on the part of those who administer the law, we may derive a clearer and more concrete conception if I cite from a few of its most authoritative sources. I will content myself with quoting from a judgment of the Supreme Court of the United States, from the charge to the jury in a capital case of a former chief justice of this Commonwealth, and from the charge in a similar case of one of England's great judges.

Said Mr. Justice Grier in the case of Winans *vs.* N. Y. & Erie R. R. Co., 21 How., 88, 101: "Experience has shown that opposite opinions of persons professing to be experts may be obtained to any amount; and it often occurs that not only many days but even weeks are consumed in cross-examinations, to test the skill or knowledge of such witnesses and the correctness of their opinions, wasting the time and wearying the patience of both court and jury, and perplexing instead of elucidating, the questions involved in the issue."

Said Chief Justice Chapman, at the trial of Andrews in this Commonwealth: "I think the opinions of experts are not so highly regarded now as they formerly were, for while they often afford great aid in the determination of facts, it often happens that experts can be found to testify to any theory however absurd." (Trial of Samuel M. Andrews, page 256.)

And in Palmer's case, Lord Campbell, in summing up to the jury, said: "With regard to the medical witnesses called on the part of the prisoner, I must observe, that although there were among them gentlemen of high honor, consummate integrity and profound scientific knowledge, who came here with a sincere wish to speak the truth, there were also gentlemen whose object was to procure an acquittal of the prisoner. It is, in my opinion, indispensable to the administration of justice that a witness should not be turned into an advocate, nor an advocate into a witness. You must say, gentlemen, whether some of those who were called for the prisoner belonged to the category I have described — that of a witness becoming an advocate." (Palmer's case reviewed in 1, Law Magazine and Review, page 332.)

Such opinions, expressed under such circumstances, frequently reiterated by lesser tribunals, provoke the inquiry, which perhaps may be difficult to satisfactorily answer, Where does the fault lie?

I take it, of course, that all comment of the kind which I have quoted, is directed rather to the method of receiving such evidence than to the nature of the evidence itself, for the severest critic would not hold that even under the prevailing law, and assuming that it cannot be improved upon, that opinion testimony, as such, should not be followed or relied upon.

If the physician were to be confined in his testimony to the bare narrative of the facts which he saw or observed, one at least of the safeguards of the community would be destroyed. The phenomena which result from the work of the murderer, the poisoner or the abortionist, as

revealed in the human cadaver, are an enigma to the layman. Though accurately described, though no detail be omitted they mean but little to his mind. To the physician, the surgeon or the toxicologist they may demonstrate with entire certainty that death was not natural, that it was caused by violence or malpractice, or by the administration of poison; or with equal certainty, on the other hand, where guilt is suspected, suspicion to be unfounded. Such certainty, however, can find expression in our courts of law in but one way, viz.: by what is known as expert or opinion testimony.

It is useless, however, to attempt to palliate the contradictions, inconsistencies, exaggerated and absurd theories which under present conditions so frequently characterize the trial of the most important issues. It is seldom that a capital case is tried, which does not result in revelations of a nature which cannot but annoy and mortify the medical profession.

Few theories, however fantastic, need go unchampioned; the question of insanity has become a byword, and it is the experience of lawyers that to testify as an expert is becoming more and more repugnant to those physicians whose evidence would be of the most value. The annals of criminal jurisprudence of the century just past furnish too abundant proof of how strikingly medical experts have been at variance in particular cases; and of what diverse and inconsistent views have been entertained upon a given state of facts, by members of the same profession, and of equal eminence, educated, perhaps, in the same schools, contemporaries in practice.

The case of William Palmer, a surgeon, for example, who was tried in London for the murder by poison of one John Parsons Cook, is a most conspicuous instance of contradictions amongst experts. Four different theories were advanced by as many physicians as to the cause of death, and the analysts called on one side and the other were wholly at variance as to the phenomena which attend the administration of strychnia.

In the case of Dr. Smethurst, tried a few years later in London, for poisoning a woman with whom he had contracted a sham marriage, the conflict of evidence, medical and analytical, as to whether the symptoms of the post-mortem appearances were ambiguous and could be referred either to natural causes or to poison, was such, that though the prisoner was convicted, the public became so agitated, and the controversy carried on by letter and petition reached such a stage, that the home secretary, who investigated the matter remarked, in stating his reasons for recommending a pardon, "that the necessity for it did not arise from any defect in the constitution or proceedings of our criminal tribunals, but from the imperfection of medical science, and from fallibility of judgment in an obscure malady, even of skilful and experienced practitioners."

And we cannot but call to mind the case of Mrs. Maybrick, tried in 1889, the result of which has been so loudly denounced as a judicial error by some who are, but by so many who are not, familiar with the evidence. The direct conflict which arose at that trial between some of the ablest medical men of Great Britain as to whether Maybrick died of arsenical poisoning, or a natural death from gastro-enteritis, is quite fresh in our minds. Doubt existing, notwithstanding the verdict, the home secretary commuted the sentence, stating that "although the evidence leads clearly to a conclusion that the prisoner administered and attempted to administer arsenic to her husband with intent to murder, yet it does not wholly exclude a reasonable doubt whether his death was in fact caused by the administration of arsenic." And although the report of the trial discloses moral evidence against her of tremendous force, yet, I take it, the question of her guilt or innocence will continue, long hence, to agitate and distract.

But who will say that the conditions of which these cases are but illustrations are not largely owing rather to the defective method of the law, than to the imperfection of science, or that we are confronted with a state of things which it is impossible to ameliorate? Surely the fault cannot be laid at the door of science. Wherever the experts in the cases above referred to were in contradiction, one of them was right and the other wrong. The failure to find traces of strychnia in a dead body is either entirely consistent with, or entirely inconsistent with, its having been administered. The analyst in Palmer's case who maintained one of these propositions was telling the absolute truth and the other was testifying to what was entirely false. Science had a faithful spokesman in one, and a false spokesman in the other. Truth was struggling to express itself through one; error through the other. It would seem, then, that it is at least the duty of the law to establish as many barriers to the progress and triumph of this species of error as is humanly possible. Under the Common Law of England, in vogue in Massachusetts and most of the American States, what are those safeguards? Whoever styles himself as a physician and who has some aquaintance with medicine, or who has had some practice, be it much or little, is regarded as competent to express his opinion as an expert, whatever may be his interest or bias.

To give an opinion as a medical expert, the law does not require that the witness should belong to any particular school of medicine. "The law has nothing to do with the merits of particular systems." (Corsi *vs.* Maretzek, 4, E. D. Smith, 1.) If the witness is a medical man and has the requisite knowledge, he may have acquired this knowledge either by study alone, although in practice he has observed no such case: State *vs.* Wood, 53 N. H., 484; Finnegan *vs.* Fall River Gas Works Co., 159 Mass., 311; or by practice alone: Mason *vs.* Fuller, 45 Vt., 29. He need not have made the subject a specialty in his practice. Nor to give an opinion as a medical expert, need the physician (except in Wisconsin where it is required by statute) be a graduate of

a medical college, or even duly licensed: New Orleans R. Co. *vs.* Albertson, 38 Miss., 247. Nor need he be at the time in practice: Roberts *vs.* Johnson, 58 N. Y., 613; Tulles *vs.* Kidd, 12 Ala., 648; Everett *vs.* State, 62 Ga., 65. Nor need he have met a similar case in the course of his reading or practice: State *vs.* Clark, 12, Ired., 151. And finally, in some jurisdictions, it is not even essential that he should be a physician or should have studied for one, provided he has acquired the special knowledge required of the medical expert: Re Toomes, 54 Cal., 515; Dole *vs.* Johnson, 50 N. H., 452.

Insanity being deemed a disease, it is the general custom of our American judges to accept all educated and practising physicians as experts, whether they have given special attention to the disease of insanity or not. ("Bishop's Criminal Law," Section 544.) And it would even seem, from a dictum of one of our courts, that, in one State, at least, nurses, accustomed to attend upon the sick, are considered experts in respect to the mental capacity of sick persons. (Fairchild *vs.* Bascomb, 35 Vt., 298.)

In an Alabama case (an action for damages for false warranty in the sale of a female slave, a species of suit which was not uncommon in slavery times) a witness was permitted to give an opinion as to the soundness of the slave, whose qualifications were that previous to 1831 (the suit was brought in 1847) he had attended a course of medical lectures, had obtained a license from the Board of Physicians of the State to practise physic, and practised as a physician for one year when he abandoned medicine for the law, and for the period of sixteen years had been and still was following that profession, the witness stating that he had continued to read medical books, had kept up with the improvements of the science, and felt competent to express medical opinions upon the diseases of women. It was stated by the court in its judgment "that the clinical practice is doubtless a most efficient mode of acquiring such knowledge, by enabling the practitioner from his own observation, to verify the assertions or theories of others, or to correct errors into which they may have fallen; and it may be, that medical opinions, not brought to this test are not worthy of much reliance as the basis of the verdict of a jury. But, if one asserts an ability to give correct opinions, upon any art or science from any acquaintance with the subject, acquired by observation and study, we cannot perceive on what ground he can be rejected because he has not been in the actual practice of his profession. This circumstance may deprive his testimony of much weight with the jury, but is no ground for excluding it."

In a late case which arose in Illinois, a physician who had practised thirty-four years, a graduate of a Chicago medical college, who, so far as appeared, had never in his practice witnessed a case of arsenical poisoning, was permitted to express his opinion that the deceased, under the circumstances shown, had died of arsenical poison. (Siebert *vs.* The People, 143, Ill., 571.)

These cases are fairly representative of the general trend of the decisions of the courts in this country upon the degree of qualification required of the medical expert. The question arises, then, whether the law has not lost sight of his true status; whether, permitting a party to call whomsoever he may find, having some general knowledge of medicine and willing to support a favorable theory, is not a departure from the true principles which underlie the admission of such testimony. There can be no mystery as to the real purpose for which experts are called. "What is their function?" says Professor Thayer in his "Treatise on Evidence." "It is just this, of judging facts and interpreting them. They are called in because, being men of skill, they can interpret phenomena which other men cannot, or cannot safely interpret. They 'judge' the phenomena, the appearances or facts which are presented to them and testify to that which in truth these signify or really are; they estimate qualities and values. We say that they testify to opinion. In truth they are 'judging' something and testifying to their conclusion upon a matter of fact. For this reason, in Germany, experts are called *judices facti*—*judices* as opposed to ordinary witnesses, *judices facti* because they do not judge as to the law, but their judgment or opinion only gives as its result a fact." In this connection, it is interesting to note that when opinions were first admitted in the English courts as testimony (those which were offered earliest appeared to have been those of medical witnesses) they were received for the purpose of enlightening the court, and if they reached the jury at all did so through the medium of the court's charge.

In an appeal of mayhem tried in 1353, the justices having failed to determine from their own inspection whether a wound was mayhem, ordered skilled surgeons from London to inform the king and his court on this point.

An ejectment case tried in 1619 involved the question of the legitimacy of a posthumous child, and the court received the testimony of two doctors of physic in regard to the period of gestation, the record of the case reciting: "So the court delivered to the jury that the said Elizabeth, who was born 40 weeks and more after the death of the said Edmund Andrews, might well be the daughter of the said Edmund."

Sometimes the assistance of experts was obtained by the court without an open examination.

In 1703, Lord Holt, upon a question as to the negotiability of a promissory note, took occasion "To speak with two of the most famous merchants in London" as to their customs in regard to the endorsement of such paper. In an earlier case, at a trial for witchcraft in 1665, Dr. Thomas Browne, "a person of great knowledge," after viewing the accused was desired to give his opinion as to what he conceived of him, and he was clearly of opinion that the person was bewitched. (Trial of Witches, 6 How. St., Trans., 687, 697.[2])

[2] For the early history of expert testimony under the English law see American and English Encyclopedia of Law. Second edition, vol. xii, p. 49.

It is difficult to perceive how an expert's position in respect to facts differs from that of a judge in respect to the law. The latter, upon all the facts, expresses his judgment as to the law in relation thereto; the former, upon some group of facts, expresses his judgment as to their significance and meaning so that the judge or jury, or whatever tribunal finally passes upon them may have a full understanding. In our law judges there are two requisites which every one is agreed are pre-eminent: learning and disinterestedness, and the faintest trace of prejudice, bias or partisanship disqualifies them. Neither little learning nor much bias, under our practice, disqualifies the expert.

We are zealous for learning and impartiality in our judges of law; why should we not be zealous for learning and impartiality in our judges of fact?

A mistake of law can always be cured by the revision of some appellate tribunal; a mistake in the opinion of the expert is often difficult to detect, and generally impossible to revise. The true status of the expert is entirely appreciated in those countries which inherited the Roman Law. In France and Germany, Italy and Austria, he is treated as a *judex facti*, a theory, which in Germany especially, is carried to its logical extreme. Whenever the man of science is there called on to express his judgment he is treated, not as an ordinary witness but as an assistant to the court, and accordingly is appointed by the court. The latter has the right to call experts at any stage of the case and of its own volition. It determines the number and exercises the selection of them. In but few cases the free action of the court in appointing experts is limited, where, for example, the law provides that in cases involving patents or copyrights, certain persons, *ex officio*, shall act as experts; and in civil cases the court is bound by the choice of both parties.

When the expert testifies he cannot be attacked like an ordinary witness; his veracity cannot be impeached because he is regarded as a part of the court and must be treated with like respect. The mode of questioning and the scope which the opinion may take are entirely discretionary with the judge and, in civil cases, at least, if the experts agree, the parties must accept their opinion as true, though not necessarily binding on the judge.

In America, the compulsory attendance of expert witnesses is of doubtful right and never exercised; in Germany and Austria whoever practices any profession or trade, or is authorized to do so, is obliged to act as an expert, when required, and the only reasons which will exempt him are those which would exempt from testifying as an ordinary witness. In Austria he swears to carefully follow the object of investigation, to truly and carefully state all his observations and findings, and his opinion according to his best knowledge, and upon his conscience, and according to the rules of his science and art. In Germany, he swears that he will give the opinion demanded of him impartially and upon his best knowledge, and upon his conscience.

The reasons assigned by German writers for so markedly differentiating the casual or ordinary witness from the expert, are principally, that the former is only a witness by chance while the latter is selected because of his standing and should not be subject to like criticism or attack; the ordinary witness is not the subject of choice and cannot be dispensed with; the expert testifies only through the choice or by the permission of the court; the casual witness at the time of the occurrence in question is frequently not impressed with the fact that he is to be called upon as a witness; whereas the expert makes his observations with that in view. The ordinary witness seldom testifies without bias for whatever we live through becomes a part of us and is affected more or less by our feelings and habits of thought and one's personality is apt to permeate his testimony; in the expert, because of his scientific training, the personal element is more likely to be eliminated. In fine, the conclusions of the casual witness are based upon his personal impressions while those of the expert rest upon scientific facts and laws. (Holtzendorff's Encyclopedia of Law, Vol. III, part 2, page 512.)

In criminal trials in Germany the medical witnesses first called to testify are those whom the State has assigned to the judicial courts after previously ascertaining their knowledge in this department. The chief of the staff of professional experts is the district or town physician the statutory regulations requiring him to be scientifically educated, properly licensed and skilled in all the three branches of medical science, medicine, surgery and obstetrics; while there is also an organized series of courts of professional experts to whose judgment the opinion of the medical men first employed may be referred. The law, however, does not exclude private physicians, and they are frequently called to testify along with the official physician and sometimes to his exclusion. (Casper's Forensic Medicine, Vol. III, page 178.)

It may not be uninteresting here to epitomize by a quotation from Casper the German practice in respect to the written reports of official experts, and its provisions for their revision: "A copy of all the medico-legal transactions of all the medical jurists in Prussia, both protocols and reports, without exception, is sent by each respective local magistracy to the provincial government, and through it, in quarterly budgets, to the Royal Medical College of the province, for its revision. The same procedure is followed in regard to all inquiries regarding lunacy or idiocy in civil law. This board, on its part, transmits their transactions, along with its remarks upon each, to the ministry appointed, in which both transactions and revisals are submitted to a super-revisal by its scientific commission, and the result is communicated both to the revising medical college and also to the medical jurists concerned, affording to the latter instruction or recognition and encouragement.

"Here we have," says Casper, "no doubt, a cumbrous official apparatus set in motion, but this arrangement is indubitably successful in its operation, inasmuch, as not only does it maintain the central courts constantly acquainted with the doings of their medical jurists, but also indubitably has its share in the elevation of the practice of legal medicine in Prussia, to a perfection hitherto, attained in no other country, a fact which must be acknowledged, and which has quite recently been recognized by a most competent authority."

In Sections 173–177 of the Code of Criminal Procedure, which we have already quoted, the cases are described in which the reference of a medico-legal report to the superior courts shall take place. The rule, and the practice in most cases, is for this report to be sent, along with the other documentary evidence, first, to the medical college of the province, and should the opinion of this board be from any cause disputed, they are then sent to the Royal Scientific Commission for scientific affairs, to obtain its superarbitrium. This is, as in the medical colleges, drawn up by two referees, who work each for himself; both of their opinions are then brought before a meeting of the commission, discussed, and that one which is approved of by a majority of the commission is accepted, signed and issued. A precisely similar sequence of professional courts is found in most of the German states. In some of the smaller ones, which possess no medical boards, the opinions of the medical jurists are sent, along with the documentary evidence, to some faculty, either at home or abroad.

One result of this legislation in Germany, which may seem to us too elaborate and perhaps artificial, is that the medical expert has at his command a series of written opinions and precedents of an authoritative nature, and embodying the best judgment of his profession. To the physician in forming his opinion, they must serve as useful a purpose as do the written judgments of the courts to the lawyer in forming his.

By sketching, perhaps at too much length, some of these features of foreign law, I would be misunderstood if I seemed to think it wise for us to model our own according to the same detail. The real keynote and underlying principle, however, of the law of Continental countries in this respect, is that the expert should be the partisan of neither side; that he should be as dispassionate and just as one of our own Massachusetts judges; that in fact as well as in theory he should be the assistant of the court. That principle, if we are to hope that at some future time the medical expert shall enjoy all the respect and credence which it is his right and the right of science that he should enjoy, must be followed in some form or other. And if we are to reform our procedure in this regard, we must, I believe, finally seek relief from that source to which already the Common Law of England and of this country owe a debt which is difficult to measure, it must be sought in the body of the Roman jurisprudence.

THE UMILLIAN MURDER.[1]

BY HERBERT B. PERRY, M.D., AMHERST, MASS.

THE Umillian murder trial is said by those who are thoroughly conversant with such matters to be of peculiar interest because of the fact that more than three months elapsed from the time that the deed was committed before any actual evidence of crime was discovered, and of unusual interest because no direct evidence at any time was introduced as testimony into the trial. The murdered man's name was Casimer Jedrusick, the convicted murderer's name was Franciszeck Umillian. For ease in description I will refer to them as Jack, the victim, and Frank, the murderer.

On the 10th of April, 1900, I was summoned by State Officer McKay to go to Granby, not knowing what the case was except that a man's body had been found. I reached the farm of Monroe Keith, two and one-half miles from Granby Centre, about 9 P.M. and was informed that a man's body had been found in an old unused well. By the aid of a ladder I went into the well, which was about 30 feet in depth, and found the remains floating, that is a naked body except for a bran sack. The body was lying with the buttocks above the water, with the upper part of the trunk lying in a northwesterly direction. On going to the surface, I gave directions, and the body was brought up by the aid of a rope, and immediately taken to an old unused building near by where I performed an autopsy. The head had been severed from the trunk at the juncture of the second and third cervical vertebræ. The body was mangled and slashed and cut in all directions. First, a punctured wound just above the right clavicle 2 inches in length, another one parallel to it, over the head of the sternum, 2 inches in length. This was also a punctured wound. There was a vertical wound extending from the middle of the right clavicle, about 14 inches long, and ending 2½ inches above the umbilicus. There was a transverse wound about 12 inches long, beginning at the middle of the right clavicle, and ending at the middle of the left. On the right side a wound in the anterior axillary line, 7 inches in length, extending from the sixth to the twelfth rib on the right side. There were incised penetrating wounds on the right arm over the biceps muscle, 2 inches long. The left arm was crushed, lacerated and torn. A transverse wound over the anterior superior spine of the ileum, two incised wounds on the left thigh, 4 inches in length, and an oblique fracture at the juncture of the middle and upper third of the left femur. There were two incised wounds in the inside of the right thigh, one 7 inches in length, and one 4 inches in length. The ribs on the left side, from the first to the ninth, inclusive, were crushed and broken. The sternum was broken and four ribs fractured on the right side. The heart and pericardium were absent, the large vessels being partially torn and partially cut. The stomach was empty except about a pint

[1] Read before the Massachusetts Medico-Legal Society, February 6, 1901.

of a pultaceous mass. The intestines were normal, uninjured except a small wound in the ileum. The lower lobe of the left lung was lacerated and torn, the right pleural cavity had been opened. The lung was collapsed but was unwounded. The body was identified positively by a deformity of the index finger of the left hand. Evidently there had been a felon sometime and the distal phalanx was atrophied and bent inward toward the median line. Another means of identification were some enormous bunions on the great toes of both feet. After the body was taken to the surface and the discovery made that the head had been severed from the body, further search was made in the well with the hope and expectation of finding the missing head. It was not found, however, but we did find the clothing which was identified as belonging to Jack. This was delivered to one of the officers.

On the 12th of April, two days after the body was found in the well, the head was found buried in the soft earth of the barn cellar of Mr. Keith and delivered to me about six o'clock of the same day. The soft parts, including the brain, were totally destroyed, so much so that an attempt at differentiating one part from another was absolutely impossible. After a careful preparation of the skull, the wounds in the bony parts were as follows: I will speak of these numerically in the order in which they seem to me to have been inflicted. First, was a wound beginning $\frac{1}{4}$ of an inch posterior to the coronal suture and $1\frac{1}{4}$ inch external to the saggital suture on the left side. This wound was $1\frac{7}{8}$ inches in length, wider at the middle portion, being $\frac{3}{8}$ inch in its widest diameter. The second wound was $2\frac{1}{2}$ inches long, beginning at the inferior temporal ridge, extending downward and slightly backward from the squamous portion of the temporal bone, destroying the styloid process of the petrous portion of the temporal bone, and extending through and dividing the pterygoid process of the sphenoid bone. The third wound was 3 inches in length, $1\frac{1}{4}$ inches from the median line over the right occipital. This wound extends backward toward the right side. The fourth wound, 1 inch in length, and $1\frac{1}{4}$ inches from the median line and parallel to it, and 1 inch internal and behind the mastoid process. The nasal, the right malar, right zygoma, lachrymal and the anterior portion of the right wing of the sphenoid were separated from the adjoining parts and absent. The right lachrymal and superior maxillary were absent. The larger half of the frontal and squamous portion of the temporal and the left wing of the sphenoid were separated except for attachment of soft parts. The inferior maxillary bone divided in the medial line, the right half absent.

Now it will be particularly interesting to endeavor to weave a theory as to just how and in what manner these blows were delivered, the circumstances and the motives for such extensive mutilation and laceration. Taking first the blows on the head, as I have already said, I have numbered the wounds, one, two, three, four, according to the order in which they seemed to me to have been inflicted. The last time Jack was seen alive was on the 31st of December, 1899, Sunday morning, shortly after 10 o'clock, by his employer, Mr. Keith, to whom he had brought a horse and carriage that Mr. and Mrs. Keith might attend church at Granby. Jack, after leaving them, went directly into the horse barn with the intention of changing his clothing and shoes and going to Granby. He sat down on a bench near where the men were in the habit of keeping their footwear, stooped down to untie his shoes. Frank came in at this time, saw Jack and in a paroxysm of long pent-up rage and fury, seized a corn-knife (which is an instrument used for cutting corn, having a blade about 2 inches in width and 18 inches in length attached to a stout oak handle) from one of three which were hanging on a beam near by. He was standing somewhat behind and to the left side of Jack as he was stooping over fixing his shoes. That was the first blow that was struck, a crushing downward sweep of a sharp instrument penetrating the skull, and driven well into the base of the brain. From the blow and the shock Jack pitched forward. Frank sprang over the prostrate body and struck again, the point of the corncutter entering the skull just at the petrous portion of the temporal, crushing through the squamous portion of the temporal bone. As the body of the now unconscious Jack writhed on the floor in death agony, other blows were rained thick and fast on the unfortunate man until death put an end to the struggle. Frank then, with speed and keenness born of desperation, opened the trapdoor in the horse barn, dropped the body, clothing and all, down into the soft, muddy, foul bottom of the cellar. To bear out this theory, let me say here that on the clothing taken from the well was found soil from the barn cellar, and inasmuch as all of the ground outside of the barn cellar was frozen hard at this time, only from the barn cellar could this mud and filth have come. Frank closed the trapdoor, then went a roundabout way into the cellar and then began the mutilation of the body that has already been described. His first thought was to destroy as far as possible all means of identification. So he hacked and cut and slashed the face until all resemblance to features was gone. Then what must be done with the body. He severs the head from the body and attempts to further cut the body up to facilitate the disposition of it. Finding it a rather difficult task, he stripped the body of its clothing, thrust it into a sack, secreting it until some time that night or next morning, then taking it, with the clothing in another sack, carrying it across the road about 150 yards, and dropping it all in the old well having previously secured a large stone from a nearby wall, which he put in the sack with the clothing to sink it. Before an examination of the clothing had been made, I was asked the question if the mutilation of the body was done before or after the clothing was removed. My opinion was that most of it was done after the clothing was removed, basing my opinion on the length of

the wounds and the peculiar characteristic appearance of an incised wound, believing it to be impossible to inflict a cut like any of these through the thick winter clothing. The examination of the clothing proved my theory correct, for in it were found only two cuts, the ones corresponding to the punctured wounds over the right clavicle and over the sternum. An attempt was made to demonstrate the presence of blood on the floor and on the corncutter, but Professor Wood, of Harvard, was unable to find any traces. This result was what might have been expected, because over the floor where this tragedy is supposed to have taken place the constant tramping and use of three months would obliterate practically any blood-stains. The rusty corn-knives would, in three months, undergo such oxidation and change from atmospheric influence, that Professor Wood gave as his opinion that if it had been there it would be a practical impossibility to demonstrate it after three months had elapsed.

There is one point of particular interest to me, because as far as I am able to determine or ascertain, nothing of the kind has ever been observed. After the autopsy and search in the well for the missing head, thoroughly chilled and tired, I went to the house of Mr. Keith, into the kitchen where Frank was sitting hand-cuffed to the officer. It being my first actual experience with a real live murderer, I was particularly curious to note his actions and to see if he had the appearance of a guilty man. While sitting there, there occurred to me suddenly a plan which had been brought out in some of the French courts, that is, the sudden accusation and startling evidence suddenly presented to the suspected criminal, noting the effect on the heart's action through the nerve centres. Frank was sitting with his knees crossed and I was able to determine approximately his pulse rate, which I counted several times, and was able to count it at about eighty beats to the minute. After a short time Mr. McKay, the district police officer, came in, sat down and said, "Frank, where is that head? What did you do with it? Did you bury it in the barn cellar"? The man made no response except "I don't know," but his pulse rate increased until I was able to count about 120 beats per minute. I was satisfied, then, in my own mind that the man knew much more about it than he was willing to reveal. The subsequent finding of the head in the cellar certainly seemed as though he did know something about it.

UPON WHAT SORT OF INFORMATION SHALL A MEDICAL EXAMINER HOLD A VIEW?[1]

BY H. M. CULLS, M.D., BROOKLINE, MASS.
Medical Examiner, Eighth Norfolk District.

Mr. President and Fellows: — The title of my paper is, as you see, a question. I do not, therefore, come before you to impart any knowledge, but rather to provoke discussion, and decision, if possible, upon a moot point in medico-legal procedure.

I am aware that the subject in the title has been several times discussed before this society, but I have discovered that there exists a difference in practice among my brother examiners as to the method of procedure upon the point which my case illustrates, namely, upon the sort of information which made me cognizant that the body of a person whose death was "supposed to be due to violence," lay within my district.

The case is as follows: F. K., while aiming to board an electric car for Boston, passed in front of an outward bound electric, and was struck on the head by the latter, causing a compound comminuted fracture of the skull, from the effects of which he died, or presumably died, for a trephining operation was done before death.

This event occurred on the morning of March 16, 1900, and F. K. died early in the morning of the next day without regaining consciousness.

I was told of the accident shortly after its occurrence by a man who was on one of the electric cars, but as he reported that F. K. was not dead when picked up and removed to a nearby house, I, of course, had nothing to do.

I heard of F. K.'s death some hours after it had actually taken place on the 17th, but merely as a rumor that such was the fact. No notice of the death came to me from the police, none from the attending physician, and none from the undertaker. I will say that the police, like myself, had only the rumor; the attending physician was unaware that any legal procedure was even remotely to be considered, and I suppose that the undertaker minded his own business.

There are two points of interest in the circumstances as related: (1) I was aware on creditable information that the body of a person supposed to be dead by violence lay within my district, and (2) that he had supposedly been killed by "an accident upon a railroad."

You will remember that the inquest law requires an inquest upon a person killed by "an accident upon a railroad," and in my digest of the law I had interpreted the word "railroad" to be a generic term which covers steam railroads, street railways, and will, if the kind comes within my reach, cover "elevated" railways.

I say, therefore, that I was in a quandary. It was my first experience with a death "supposed to be due to violence" in which I had not received a "notice" sufficiently straightforward to cause me to take action. Yet I was convinced that I was specifically instructed by the law to hold an inquest in deaths after such a manner as this. It is natural that when in doubt one should turn to some one of greater experience than oneself, to call a consultation, so to speak, so I telephoned Dr. Draper of Boston, and stated the case as above. Dr. Draper informed me that it was his custom to consider deaths upon the street railways as coming under the law requiring inquests, but that it was no part of a medical examiner's business to hunt around after the evidences of a death whose

[1] Read before the Massachusetts Medico-Legal Society, February 6, 1901.

announcement had not come squarely to his ears.

With the first part of the reply I entirely agreed, but with the second part I confess I was not satisfied. However, I acted upon it as a whole and did nothing. The sequence was that having been called by the undertaker on the 19th, two days after the death, to sign a certificate for cremation, I learned the "cause and manner" of the death, and called an inquest in accordance with the practice in Boston and my own preconceived ideas of propriety.

In looking back over the *Transactions* of this society, I find that our subject has been but seldom touched upon. Certainly nothing on record from the lips of a medical examiner defines any rule to govern in the premises, if perchance any rule can govern. I have quoted to you the opinion of Dr. Draper, and I now quote to you the opinion of an officer of the law.

District Attorney Asa French, in a paper entitled "The Duties of a Medical Examiner Considered in their Practical Relations," read before this society June 10, 1879, says (Vol. I, No. 2): "What constitutes a notice to the first inquiry? I answer, any reliable information of the fact. The notice need not be a formal one; whenever and however the medical examiner becomes aware that a dead body has been found under circumstances of suspicion, his duty is to attend and take charge of it without delay."

This is a pretty clear definition of the sort of information which should set a medical examiner to work investigating, but unfortunately the words "under circumstances of suspicion" are somewhat ambiguous. These words materially limit the definition's scope, unless we conclude them to be synonymous with "supposed to have come to his death by violence." I am forced to believe that Mr. French's words were meant to be synonymous with the last clause quoted, because it seems to me to be their safest interpretation for guidance in the future. For instance, there was no suspicion of foul play in my case, but there was a very strong, in fact positive, opinion among the friends of the deceased that the death was in no way due to any fault of F. K.'s.

Now, unquestionably, it is just as much our duty to establish innocence as guilt, but if doubt, which cannot be swept away by view and autopsy exists, as to some one's negligent or criminal act, neither innocence nor guilt can be determined without an inquest. Mr. French's words, "under circumstances of suspicion," would give me just as much *reason* to act as the words "supposed, etc.," for there was certainly a "suspicion" that the motorman on the outward car was at least negligent, in fact this was the finding of the judge after the inquest.

Other quotations more or less to the point may be cited. In a discussion of a paper by Dr. Mead (June 12, 1894, Vol. II, No. 5), Dr. Munsell quotes a letter from District Attorney George Marston, who says, "You had better make ninety-nine uncalled for views than let the one-hundredth go by." We may draw something from this by inference.

Attorney General Knowlton, in a paper read before this society February 3, 1897 (Vol. II, No. 7), is clear enough in his definition as to who has a right to "suppose" that a death is by "violence." He says: "Who is to make the supposition? I answer, anybody, anybody." Would that he were as clear a little further on when he says: "I am told that there is some hesitation on the part of some of your body as to how far they should proceed upon rumors; . . . no one can lay down rules; the medical examiner must not be influenced by considerations of the county treasury, or by objections of county officers against the expense, but by considerations which are founded upon his own good sense and experience"!

All agree that the medical examiner may be in doubt at times and in cases. I believe that our guild will agree that rules by which to make up one's mind as to the exact procedure in all cases cannot be laid down. Fortunately, all medico-legal authorities are in accord that we should act for the best interests of the Commonwealth, and they define the best interests of the Commonwealth to be, to quote the words of Dr. Amory, "to err in cases of doubt upon the side of too much rather than too little investigation." (Oct. 5, 1881, Vol. I, No. 4.)

LEUCOCYTOSIS AND TYPHOIDAL PERFORATION.

FROM THE MEDICAL CLINICS OF THE MONTREAL GENERAL AND ROYAL VICTORIA HOSPITALS.

BY COLIN K. RUSSELL, B. A., MONTREAL, CAN.,

Voluntary Assistant, Royal Victoria Hospital.

MUCH has been written of late on the subject of leucocytosis in typhoid fever, and special value is attached to its diagnostic importance in impending or actual perforation. Upon what degree of leucocytosis we ought to depend has not been elucidated, though one realizes that the more marked this sign is, the greater may be our assurance in deciding on the presence of a serious complication.

As to the nature of the leucocytosis, differential counts have shown that the most marked relative increase occurs usually in the mononuclear cells, a condition to be expected in view of the preponderance of lymphatic gland involvement in enteric fever. Experience in the hospital wards with cases of typhoid fever has shown that the leucocyte count may not always be accepted off-hand as positive proof of the nature of the complications, even where a perforation has been suspected, for other conditions resembling perforation in their symptoms may yield marked leucocytoses, while, on the other hand, in cases of actual perforation there may be sometimes even a diminution of the number of white cells found in the blood.

In 37 examinations of uncomplicated cases of typhoid fever, the leucocytes showed a variation

between 2,000 to 12,000, an average of about 6,500. All counts were made as remotely as possible from the digestive period in order that I might obtain more uniform results.

Of the number of complicated cases examined the blood counts have shown most instructive and interesting results, results which, while showing the importance and diagnostic value of blood counts in enteric fever, nevertheless teach the important lesson that grave exceptions may occur, and that one may readily be led into error by attaching too great a significance to leucocytosis as a sign of perforative peritonitis. A few examples will readily explain the results obtained.

Case I. *Typical case showing value of blood examination; very doubtful signs of perforation; leucocytosis 28,000; operation: perforation found; recovery.*—A boy, age 7, was admitted from Dr. C. W. Vipond's practice to the Royal Victoria Hospital on the eleventh day of the disease. The malady had been attended by the usual symptoms incident upon incipient typhoid fever, and on the tenth day he complained of gradually increasing pain in the abdomen, especially in the right lower quadrant. There was no alteration in the pulse or temperature to indicate radical change, nor did the abdomen present, apart from slight general tenderness, any rigidity, distension or obliterated liver dulness. He vomited once a small amount of food. Dr. Garrow saw him in consultation and ordered his immediate admission to the hospital where he was carefully watched for the next few hours, and the blood counts by Dr. Tooke showed in four different examinations an average of 28,000 white cells. A few hours later he was thought to have slightly increased rigidity and Drs. Bell and Martin recommended operation which Dr. Garrow performed. The perforation, which was promptly discovered near the mesenteric attachment of the ileum, was sutured, and the boy made a good recovery.

After the operation the leucocytes diminished, two days later being 19,000 and two weeks subsequent to the operation, 9,000.

This, then, was a typical case to illustrate the value of leucocytosis, which was the main feature on which to base a conclusion as to the necessity for operative interference.

Case II. *Signs of perforation, definite; leucocytosis twelve hours after perforation occurred only 12,000; operation: recovery.*—Mrs. T. This patient was admitted to the Montreal General Hospital under Dr. Shepherd as an emergency case. She had developed signs of perforation on the fourteenth day of the disease and was operated upon soon after admission.

In this case I was enabled to examine the blood immediately before operation, and the patient, apart from the local condition in the abdomen, was in a good state for operation. The white cells numbered only 12,000, but the perforation signs were characteristic. Operation was performed and the bowel duly sutured. The patient enjoyed an uninterrupted recovery.

Case III. *Peforation; leucocytosis 4,800; operation: death.*—Mrs. V. Admitted to the Montreal General Hospital under Dr. Molson on the sixteenth day of the disease, with a blood count of 6,100 and no evidence of complication. Four days later the classical signs of perforation suddenly developed; a careful blood count was made by Dr. Henry three hours later, showing only 4,800 white cells. Operation was performed, the ruptured bowel discovered and promptly sewed, as were also six other ulcers which had already nearly eroded the thickness of the intestine. The patient unfortunately succumbed to the disease.

Case IV. *Signs of perforation; leucocyte count averaged 14,500; operation: no perforation found; recovery.*— Mr. St. L. This case was one of two which presented features of unusual interest and instruction. The patient came to the Royal Victoria Hospital under Dr. W. F. Hamilton's care on the tenth day of the disease, presenting the typical signs of typhoid fever with reaction to the Widal test. For four days the disease ran the usual uncomplicated course, when suddenly, on the evening of the fourteenth day of his malady, the man developed pain in the abdomen, chiefly in the left lower quadrant. The pain gradually increased until within thirty-two hours marked rigidity was present. Dr. Ballantyne made two blood counts in succession at this time, the white cells numbering respectively 16,000 and 13,000, an average, therefore, of 14,500, before operation was commenced.

The operation by Dr. Garrow, however, showed neither signs of perforation nor peritonitis; the condition of the bowel being nearly such as is to be expected at that stage of the disease. The abdominal wall was again closed, and the patient has since run the usual favorable course of the disease without complication. The blood count made on the day following the operation revealed, in the average of three counts, less than 10,000 white cells.

Case V. *Signs of perforation; leucocytosis 17,000; operation: no perforation found; mesenteric glands unusually large and swollen; recovery.*— Miss O. In this patient, age thirty-nine, at the Montreal General Hospital under Dr. Lafleur, the course of the disease had been favorable up to the seventeenth day, when, one hour after a bath, pain suddenly developed in the right iliac region, progressively increasing and with gradually developing rigidity. The tenderness and distention became so marked as to arouse the grave suspicion of perforation, and a blood count was made showing 17,000 white cells. Two hours later there were 14,000 leucocytes, and after a period of two hours more the cells were reduced to 10,500; showing, in other words, for typhoid fever, a moderate degree of leucocytosis.

Upon consultation with Dr. Armstrong, operation was decided upon and performed a few hours later, the local symptoms not having shown any signs of abatement. The laparotomy, however, failed to reveal any perforation, though two of the ileocecal glands were unusually tense and swollen.

In the absence of anything further the abdominal wound was closed, and the patient made an uninterrupted recovery, no further signs of perforation developing.

CASE VI. *Very indefinite signs of perforation; blood count 14,000 to 12,000; delay in operation to watch progress; sudden general peritonitis; leucocytosis 32,000; operation: death.* — Mr. A. This patient, an adult male, was admitted to the Royal Victoria Hospital under Dr. Martin on the twelfth day of the disease, with the characteristic symptoms, signs and reactions of enteric fever. Two days later he developed rather suddenly some pain in the region of the spleen, with tenderness on pressure over the ribs in that area; there was no rigidity nor abdominal tenderness elsewhere; the pulse remained unaltered and the leucocytes numbered 12,000. The condition remained thus for the following eighteen hours except that his general condition seemed slightly more serious and some tenderness developed in the right iliac fossa as well. The pulse, however, which had been about 96, was not raised during this time over 104, and there was still no increase in the rigidity.

The blood examinations were made every three hours by Dr. Tooke, and showed never more than from 12,000 to 14,000 white cells. For this reason, and more especially after the experience as recorded in Cases IV and V, operation was not immediately performed. The patient a few hours later became suddenly collapsed, with signs of general peritonitis, vomiting, rigidity, great tenderness and a rapid pulse. It was then, for the first time, that the blood count rose appreciably, 32,000 white cells being present in the cubic millimetre. The 2 previous cases recorded had had a higher leucocyte count without perforation, and with signs which in the early stage of the malady were far more characteristic of perforation, and yet the operation had revealed nothing.

With all the signs of collapse in this case and a pulse which could scarcely be felt when Dr. Bell saw the case before operation, the recovery after operation was not to be looked for, and the patient succumbed a few hours later.

REMARKS.

That one may obtain marked variation in the leucocyte count in typhoid fever is well known, and in Dr. Cabot's comprehensive observations he has shown that even where no complications are evident, one may obtain an average of over 15,000 white cells to the cubic millimetre. Further, that where certain abdominal complications other than perforation exist, the leucocytes may rise to a very marked degree. Moreover, in the case cited by him of phlebitis the white cells numbered 16,200 to the cubic millimetre.

Name.	Date.	Day of Disease.	Temp. at Time of Exam.	Relation in Time to Last Meal.	Nature of Diet.	White Cells.	Complications.
1. Drysdale.	Dec. 31, 1900.	13th.	103.2°		None.	22,000	Perforation.
2. Talbot.	Oct. 2, 1900.	14th.	104.3°	2 hours.	Liquids.	12,000	Perforation. Emergency case; count made twelve hours after perforation; operated on and perforation sutured; recovery.
3. Vosburg.	Nov. 27, 1900.	20th.	104.3°	2 hours.	Liquids.	4,800	Perforation. Abdominal pain between 7.30 to 8 A.M.; tenderness, tympanites and evidence of perforation, pulse rapid and irregular; operated on, and one perforation and six ulcers sutured; death.
4. St. Louis.	Dec. 20, 1900.	14th.	101°			14,000	Mesenteric glands enlarged. Operation; no perforation found.
5. Ogilvie.	Nov., 1900.	17th.	102°			17,000	Symptoms of perforation. Operation; no perforation present.
6. Anderson.	Jan. 7, 1901.	11th.	97.2°	2 hours.	Liquids.	30,000	Several previous counts at different intervals gave an average of 22,000.
7. Miller.	Dec. 31, 1900.	18th.			Liquids.	13,000	Cholecystitis.
8. Laundry.	June 29, 1900.	18th.	98.4°	2 1-2 hours.	Custard.	13,000	Otitis media, which later disappeared.
9. Kelly.	June 30, 1900.	46th.	99.4°	3 hours.	Milk, toast, eggs, custard.	20,000	Simple bronchitis.
10. Powers.	July 3, 1900.	22nd.	99°	2 hours.	Liquids.	12,000	No complication.
11. Demers.	June 30, 1900.	18th.	98.4°	3 hours.	Liquids.	13,000	Septicemia; died; no perforation.

In a number of complicated cases of typhoid fever which I have examined, the same results could be determined; in one patient in whom the only discernible complication was a simple bronchitis, there were 20,000 leucocytes to the cubic millimetre. In a case of cholecystitis 13,000; in one of mild middle ear disease 13,000, and in a case complicated by general sepsis, the white cells, as was to be expected, showed a similar increase, namely, 13,000 to the cubic millimetre. The cases above cited lead in the main to the following conclusions:

(1) That in perforation it is the general rule to have a leucocytosis, but that the degree may vary within wide limits.

(2) That the leucocytes, while appearing as a rule early, may not be at all marked until the general peritonitis and collapse have supervened.

(3) That there may be an utter absence of leucocytosis with marked perforation and peritonitis; in fact, that the cells may be lower than normal.

(4) That with typical signs of perforation and a definite leucocytosis there may be no such complication present, and an operation may be performed unnecessarily.

(5) That a marked degree of leucocytosis may occur in complications other than perforation, for example, bronchitis, cholecystitis, etc.

(6) That with pain and tenderness in the abdomen, coming on suddenly during an attack of typhoid fever (and in the absence of evidences of cholecystitis or other definite complication), and a distinct leucocytosis, even without other signs of perforation, an exploratory operation is justified, even advisable, thereby obviating the dangers of a fatal issue from too great a delay. The exploratory operation in Cases IV and V, done unnecessarily, resulted in no bad consequences, and the patients made a satisfactory recovery.

In conclusion I would like to record my indebtedness to Dr. C. F. Martin for assistance in carrying out my little investigation, and to the other clinicians of the hospitals for kind permission to use their material.

Clinical Department.

CONTUSION OF THE ABDOMEN; NO EXTERNAL WOUND; RUPTURE OF THE DESCENDING COLON; FECAL ABSCESS; DRAINAGE; SUTURE OF RUPTURED GUT; RECOVERY.

BY CHARLES L. SCUDDER, M.D., BOSTON.

J. H. M., thirty-six years old, was caught between a station platform and a moving railroad car. He was crushed. A few hours later he entered the accident room of the Massachusetts General Hospital, service of Dr. A. T. Cabot, in a condition of moderate shock. The temperature was 100°. Over the left iliac crest was an hematoma slightly tender and fluctuating. The urine was smoky in color. The white blood count was 10,200.

The first night he vomited three times, the vomitus consisting of the stomach contents. The next morning the abdomen was slightly distended. The third day all food by mouth was stopped on account of nausea. On the fifth day he had two fecal dejections. There was no more vomiting. On the sixth day the temperature was 101°. The abdomen was less distended. On the left side in the loin the hematoma was tender and fluctuating and the skin over the area was red. Under ether the swelling was opened and a large fecal abscess was evacuated. The cavity toward the abdominal side was bounded by the small intestine, descending colon and omentum. The muscles of the abdominal wall had been torn from their attachments to the iliac crest. At the extreme depth of the abscess was discovered an opening into the descending colon which admitted the tip of the forefinger. The abscess, so well separated from the peritoneal cavity, was thoroughly evacuated and its wall cleansed with sterile water. Gauze drainage was used. After the sloughing portions of the wound had granulated, some eight weeks after the accident, an unsuccessful attempt was made to close the fistula. Ten days later a second attempt at closure succeeded. The edges of the fistulous opening were refreshed, all tension in the part concerned was removed and the gut was closed with silk sutures.

The particular interest in this case lies in the fact that the rupture of the bowel was not attended by such symptoms as would ordinarily lead one to suppose that a serious injury had been received.

A suppurating hematoma was evident. The rupture in the gut was concealed.

The very important sign that was misinterpreted was that of vomiting. This symptom, instead of being explained by the patient's statement that he had eaten something indigestible before he was injured, should have suggested a lesion of the bowel, or at least serious involvement of the peritoneum.

Vomiting once of stomach contents after an abdominal contusion is of no especial importance. Continuous, unexpected vomiting without any apparent reason is significant of an intestinal lesion. This is true in spite of the absence of other signs of involvement of the peritoneum.

During convalescence this patient had a pneumonia and a phlebitis of the left thigh and leg.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

THE INFECTIOUS AND TOXIC ORIGIN OF NERVOUS DISEASES.

At the tenth congress of the Societá Freniatrica Italiana in Naples last October, one of the subjects for formal discussion[1] was the intoxications and infections in the pathogenesis of mental diseases and neuropathics. This discussion was opened by D'Abundo, who maintained that infections and intoxications are the most frequent sensible and active factor in the pathogenesis of nervous diseases in general, in every period of life both intra-uterine and extra-uterine. The toxic infectious heredity (as syphilis or alcoholism) facilitates in the descendants the evolution of toxic-infectious neuropathies with a classical anatomico-pathological basis. Infections and intoxications in the progenitors, or in the mother during gestation, very often produce in the fetus very marked retardation of the processes of myelinization of the different systems of nervous connections. Some degenerative forms of neuropathy are often to be regarded as due to defective cerebral or spinal organization, the result of toxic pathological processes in the embryo which have been healed. The

[1] Rivista Sperimentale di Freniatria, xxvi, 919, December, 1900.

infections and intoxications of the nervous system facilitate the evolution of secondary intoxications, which feed, re-enforce and complicate the clinical phenomena and result in complex forms due to multiple intoxications. The toxic-infectious agents may act upon any part of the nervous system, giving rise to peripheral or central, systemic or disseminated localizations, and resulting in acute or chronic neuropsychoses. Mental confusion represents the commonest clinical type of toxic-infectious action, although other forms of psychopathy may also have equally a toxic origin. Acute delirium may be regarded as a clinical manifestation due to various toxic-infectious agents, not merely the special bacillus described by Bianchi and Piccinini, but also the colon bacillus, the streptococcus and others. The toxic-infectious origin of general paralysis is greatly strengthened by each new study of its etiology. The clinical manifestations of infections and intoxications of the nervous system are the result of more or less pronounced disturbances of nutrition, which in certain phases are susceptible of restoration to the normal, even when the symptoms make us doubtful of a cure. The treatment, until we know precisely each morbid cause, should favor the elimination of the toxic products and try to neutralize or check the production of secondary intoxications.

Agostini, the co-referee in the debate, divides the toxic-infectious agents into three classes: The chemical poisons entering the system from without; the toxic-infectious processes; and the intoxications that are purely endogenous, the so-called auto-intoxications. Alcohol, naturally, takes the chief place in the first class, as giving rise to the most severe and diffuse forms of nervous disease, from multiple neuritis to neurasthenia, and also to various psychopathies, transitory mania, delirium tremens, and even forms closely resembling if not identical with general paralysis. Of almost equal importance in Italy is pellagra, due to the poison of diseased maize, which, like other chronic intoxications, may cause severe systemic diseases of the spinal cord, peripheral neuritis, and diffuse alterations in the cells of the brain. In addition to the direct toxic action of the disease, other forms of auto-intoxication may arise secondarily from the disturbances in the alimentary canal. The children of the pellagrous, too, may present various forms of severe nervous disease, degeneration, infantilism, idiocy, and the like, similar to the forms seen in the children of alcoholic or syphilitic parents. The influence of the true infectious diseases is well known; even the milder forms, such as influenza, often giving rise to severe diffuse affections. Among these acute delirium has been of late the object of special study, and in a considerable number of cases various micro-organisms have been found in the blood or the meninges. In some cases where the delirium is secondary to other disturbances, Agostini suggests that the blood loses its bactericidal power under the influence of the primary disease, thus facilitating the invasion of the brain by some of the commoner forms of bacteria. The so-called auto-intoxications are the forms which are today most in doubt, since we have not yet been able to isolate the poisons or to determine absolutely the method in which they are formed. In health the vital chemical processes of various tissues develop certain toxic substances, which are either excreted or destroyed or neutralized by certain organs, as the liver, the thyreoid, the supravenal capsules, the lymphatic glands, etc. In diseased conditions this excretion or destruction is impaired. Overwork or disturbed nutrition may increase the production of these toxines, and provoked action of certain glands (as the thyreoid in myxedema or the pituitary gland in acromegaly) may also give rise to auto-intoxication. Most of these toxines originate in the alimentary canal. Among the commoner symptoms to which such toxines may give rise are the familiar ones of mental torpor, physical prostration, irritability, somnolence, vertigo and headache. Clinically, also, the relation between convulsions and acetonuria, and tetany and gastric fermentation have had an important bearing upon the doctrine of auto-intoxication, as well as the frequent co-existence of certain psychoses with digestive derangements.

On the laboratory side many studies have been made of the gastric juice, the urine, the blood-serum, the sweat and the cerebro-spinal fluid in regard to toxicity and bactericidal power. These studies have not as yet given constant results, from which definite conclusions can be drawn, but there is an increasing amount of evidence showing that in various nervous and mental affections thought to be due to auto-intoxication, the various secretions and the blood show decided departures from normal in regard to toxicity, bactericidal power and the like. Pathologically, the changes found in these conditions are extremely similar to those found after intoxications from without or after known infections. The same clinical phenomena and the same changes in the neurones may be found, for example, after poisoning by alcohol, or after infection by typhoid, as after this hypothetical auto-intoxication. It therefore seems logical to assume that these unknown agents have a similar pathogenetic action and provoke nervous and mental disturbances in the same way as the poisons and infections whose nature we know. In such conditions, moreover, treatment directed against auto-intoxication, especially auto-intoxication from the alimentary tract, seems to promise the best results.

REFLEXES IN TYPHOID FEVER.

Remlinger[2], from a study of the reflexes in 100 cases of typhoid fever, has found them exaggerated in 32 cases, unaltered in 22, diminished in 17, and abolished in 29. There is no definite relation between the state of the reflexes and the form of the typhoid, but exaggeration of the reflexes was seen chiefly in grave cases and the ataxic and ataxodynamic forms. The normal condition was seen in the benign forms. We cannot draw an

[2] Rev. de Méd., xxi, 46, January, 1901.

unfavorable prognosis from the diminution or absence of the reflexes. Whatever the condition of the reflexes during the progress of the disease, there is a decided tendency to exaggeration at the period of convalescence. Ankle clonus was found in 20 cases, often on only one side. It usually coincides with an exaggeration of the other reflexes, but it may occur when they are normal or even absent, even when the tendon Achilles reflex is absent. It is sometimes seen at the moment of a fall in temperature, coinciding with profuse sweats or polyuria. In such cases it may be considered a true critical phenomenon. Patellar clonus is also seen, but this is always associated with exaggeration of the knee jerks. The cutaneous reflexes show little that is remarkable, but the great toe is never extended. The explanation of the changes in the reflexes may perhaps be referred to slight changes in the spinal cord, such as various observers have found, but Remlinger does not consider the possibility of changes in the peripheral nerves, such as are often found in the various acute infections. The existence of ankle clonus when the Achilles tendon reflex is lost is not easily explained on any hypothesis, unless, perhaps, we consider it a simple phenomenon of idiomuscular contraction.

Lévi[3], on the other hand, has found the Babinski reflex, the dorsal extension of the great toe, in 10 out of 20 cases of typhoid fever. All the cases recovered; 2 presented symptoms of mild, acute myelitis and 1 had temporary retention of urine. None presented signs of meningitis. In 18 of the cases the tendon reflexes were exaggerated, and in 2 they were normal. In 5 cases ankle clonus and the Babinski reflex coexisted, in 4 cases clonus existed without the Babinski reflex, and in 5 cases the Babinski reflex existed without clonus. The dissociation of the two symptoms, the Babinski reflex and ankle clonus, must be explained by the hypothesis that the lesion causing the Babinski reflex is different from that causing ankle clonus. The exaggeration of the reflexes, ankle clonus and the Babinski reflex all indicate that the spinal cord is frequently affected in typhoid fever, and, after a period of latency, chronic myelitis may develop, especially if there be any new intoxication or infection. In regard to the prognosis of the typhoid fever itself, the existence of a Babinski reflex does not add to the gravity, as all the cases presenting it recovered, while some, which did not have a Babinski reflex, died.

BRACHIAL PARALYSIS.

Grenet[4] distinguishes the various forms of paralysis of the brachial plexus according to the portion of the plexus involved. These paralyses may be motor, sensory or mixed. He distinguishes various portions of the brachial plexus: the intravertebral portion, the extravertebral portion, the plexus proper, divided into three segments, and the terminal branches. There are as many forms of the mixed paralyses as there are portions of the plexus, and they can be distinguished by the examination of the collateral nerves. The root situation of a superior paralysis is recognized by the paralysis of the supraspinatus and infraspinatus muscles, which are innervated by the suprascapular nerve. The intravertebral situation of an inferior root paralysis is recognized by paralysis of the serratus magnus. The inferior root paralysis of the first portion of the intravertebral segment (before it leaves the intervertebral foramen) is recognized by disturbances of the pupil, unless the lesion is beyond the sympathetic anastomosis. There is no marked difference clinically between an extravertebral inferior root paralysis and an inferior paralysis of the first segment of the plexus.

All the above forms, however, are of secondary importance; the two chief clinical forms are those of the root type and of the terminal type. The paralyses of the plexus proper are accessory forms dependent upon one or the other of those two great types. Pure motor paralyses result ordinarily from an isolated lesion of the anterior root, and a lesion of at least two roots is usually required to produce paralysis. Pure sensory paralyses are always due to intravertebral lesions of the posterior roots. Individual variations in the sensory distribution seem very great, for a lesion of one root may sometimes cause sensory disturbances, while, on the other hand, a lesion of three roots may not cause any such disturbance. There may sometimes be a limited anesthesia from a lesion of a single root, when other roots supplying the same region are intact. Paralyses of the root type are characterized by the localization of the disturbances in a particular group of muscles and by the special distribution of the anesthesia. Paralyses of the terminal type are characterized by the localization of the symptoms in the exact region of one or more peripheral nerves. Paralysis of the peripheral nerves, however, may resemble a root paralysis when several nerves are involved. Hysteria may be recognized by the mode of distribution of the sensory disturbances.

NEURITIS.

Vyrouboff[5] has made an elaborate pathological study of a case of multiple neuritis presenting also the familiar symptoms of the so-called polyneuritic psychosis. He found the whole neuro-muscular system and all the segments of the central nervous system affected, the changes being of toxic origin. In the nerves and muscles he found simple atrophy of the nerve and muscle fibres with primary degeneration of both sets of fibres; the nerves showed the peri-axillar neuritis of Gombault. The cells of the spinal ganglia showed chromatolysis and fatty and pigmentary degeneration, or more rarely, secondary chromatolysis. In both the central and peripheral fibres of the ganglia there was a breaking up of the myeline which could be followed into the posterior roots and into the cord. In the posterior columns of the cord there was an ascending degeneration

[3] Rev. Neurol., viii, 1005, Nov. 15, 1900.
[4] Arch. gén. de méd., October, 1900.
[5] Vratch, p. 377, 1900; Ref.: Rev. Neurol., ix, 19, January 15, 1901.

of the long systems of exogenous fibres extending to the nuclei of the columns, and degeneration of the short systems of fibres which enter the gray matter through the posterior horns. The cells of the anterior horns were diminished in number and showed primary chromatolysis and fatty and pigmented degeneration. The anterior roots and also the roots of the cranial nerves were degenerated. The degeneration in the pyramidal tract could be traced upwards from the sacral region of the cord, through the decussation of the pyramids in the medulla, the pyramidal tract in the pons and crus and the internal capsule to the motor convolutions in the cortex. In the cerebellar systems there was degeneration of the direct cerebellar tract, of the arciform fibres of the cerebellar cortex, of the large cells of the granular layer, of the cells of Purkinje and the neighboring fibres, and in all parts of the anterior cerebellar peduncle, the red nucleus, the tract to the optic thalamus, and the cells of its external nucleus. Degeneration was traced in the fundamental fasciculus of the antero-lateral column and in Gower's tract up to the pyramids. The internal fasciculus of the lateral column was everywhere intact. The most marked alterations in the cerebral cortex were found in the parietal lobe; here there was a diminution in the association fibres and a diminution and fatty and pigmented degeneration of the cells. The combination of the clinical symptoms of the psychosis, which consisted of mental confusion and disturbance of orientation in time and space, with the anatomical lesions of the parietal lobe were regarded as confirmatory of Flechsig's hypothesis that a lesion of his posterior association centre in this region leads to confusion and the impossibility of orientation in time and space.

In the discussion of Vyrouboff's paper Bechterew maintained that the cortical lesions in the polyneuritic psychoses were incontestable, and that these cases were confirmatory of Flechsig's claim that these parietal centres contain only association fibres destined for the higher mental functions. Although the lesions in these cases are more extensive than those often found, they add further confirmation to the opinion that is steadily gaining ground that multiple neuritis is not an affection of the peripheral nerves simply, but that in very many cases it is an affection involving a considerable portion of the central nervous system as well.

The earliest symptoms of multiple neuritis are usually considered to be paresthesia or paresis. Popoff[6], from a study of four cases, shows that there is a quantitative and qualitative change in the electrical excitability of the nerves and muscles of the extremities for some time before these other symptoms appear. These clinical observations agree with the recent anatomical researches of Braun, who slowly poisoned dogs and rabbits with alcohol and found changes in the cells of the brain and spinal cord and degenerative atrophy of the nerves before there was any disturbance of motion or sensation. The disappearance of electrical excitability with persistence of voluntary motion, is probably explained, like the reappearance of voluntary motion during convalescence before the return of electrical excitability, by the hypothesis that the electric current is conveyed by the myeline sheath and voluntary motion by the axis cylinder process. Popoff's investigations are of great importance in prophylaxis. By careful electrical examination the first onset of neuritis may be detected in those exposed to such poisons as alcohol, lead or arsenic, the patient may be removed from the iufluence of the poison and the disease may thus be arrested in its early stages, before it attains the severity or the hopelessness that it manifests later.

STATED meeting, March 19, 1901, E. FRANKLIN SMITH, M.D., chairman.

DISCUSSION ON DIABETES MELLITUS.

DR. HENRY S. STARK read a paper on

DIAGNOSIS AND PROGNOSIS.

It was generally assumed, he said, that the diagnosis of the disease depends on (1) The detection of glycosuria, and (2) the proper interpretation of certain deviations from good health. Having spoken of the importance of an early diagnosis, he mentioned two circumstances which might mislead the observer, namely, a comparatively low specific gravity and a small amount of sugar in the urine. Sometimes, also, the sugar present fails to reduce the cupric oxide. In view of the unascertained pathogenesis of diabetes mellitus, the diagnosis of the disease is not always an easy matter. It is well known that glycosuria may result from overindulgence in carbohydrates, from shock, from the use of anesthetics and a number of other causes, and yet the patient have no real diabetes. It is only when the glycosuria is constant or recurrent, and is attended with such other symptoms as polydipsia, polyuria and failing nutrition, that we can be assured that the latter is present. In other words, the characteristic syndronic, in connection with glycosuria, is necessary for the diagnosis. Among the other signs frequently noted are periodic attacks of headache, fatigue after slight exertion, and failing vision, slow in the aged and rapid in the young. Among the nervous symptoms are irritability of temper, moroseness, and absence of patella reflex.

As an aid to diagnosis bacteriology has been of no service, and examination of the blood has not as yet given any satisfactory results, although the blood-staining methods of Bremer and Williamson seem to promise something in the future. The tests for glucose, the only one of the carbohydrates

of clinical interest, are innumerable. None of them, however, is infallible, and perhaps the nearest approach to a perfectly reliable one is the great fermentation test of Roberts. Fehling's test still holds its own for practical utility, but it must always be borne in mind that there are a number of other substances besides glucose which may reduce copper. The secret of success is in making control contests. Some of the most sensitive tests are the most unreliable. For general office use one of the most delicate, accurate and satisfactory is that by the saccharometer devised by Dr. J. Rudioch, of New York, which he describes in a contribution to the Festschrift in honor of Dr. A. Jacobi.

The majority of cases are amenable to treatment, and an opinion as to the prognosis should never be expressed until after the patient has been under observation for a considerable time. In making a prognosis a number of circumstances must be taken into account. Among these are the following: (1) Age. In children the disease is rapidly fatal, and old age is an advantage. (2) Power of assimilation of carbohydrates. (3) Early recognition of the disease. In this connection Dr. Stark dwelt upon the importance of frequent examinations of urine in health and expressed the opinion that all our patients should be instructed to have specimens examined regularly twice a year. In this way diabetes, as well as other diseases, could be detected in their incipiency, and this would afford a great advantage in the way of efficient treatment. (4) The appearance of intercurrent diseases. (5) The condition in life. (6) The amount of urea and the presence of acetone, diacetic acid and other organic substances in the urine. (7) The capacity of the system to absorb fats and proteids. All cases of diabetes may be divided into three types, the mild, the medium and the severe.

DR. H. STERN read a paper on

ETIOLOGY AND PATHOGENESIS.

He said he had found that in eleven years (1889–1899 inclusive) there were reported 1,867 deaths from diabetes mellitus in New York City. Of these 931, or nearly 50%, were in females. Yet the statement had been generally accepted that this affection occurs two-and-a-half times as often in men as in women. Among negroes there were only 15 deaths from diabetes in the eleven years. The Hebrews and the Irish each represented 25% of the mortality — a result which he attributed to in and in breeding. Diabetes is very frequent among the poorer classes, and of 102 males who died in the year 1899, 66 were residents of tenement houses.

For clinical purposes we may trace the affection to one or more of the following causes:

(1) Excessive ingestion of glucose: Alimentary glycosuria.

(2) To diminution, functional disturbance, or excessive or abnormal disintegration of the erythrocytes (glycosurias following the introduction of poisons and toxines, or the perverted function or removal of certain glands — pancreatic diabetes, seegen's grave diabetes): Hematogenic diabetes or glycosuria.

(3) Traumatism: Neurogenic glycosuria.

(4) Interference with the glycogenic function of the liver to such an extent that the carbohydrates are not normally utilized: Common or hepatigenic diabetes.

(5) General protoplasmic deterioration and plasmolysis: Diabetic deterioration.

DR. STERN thought that the foreign element in the erythrocytes of diabetes, found first by Bremer, and met with by himself in over 300 cases, was the possible pathogenic substratum of diabetes. He recognized this as early as 1896. His supposition was that the oxygen had been partially displaced from its hemoglobin combination by carbon monoxide, of catabolic origin. The abnormal element in the cellular substance of the erythrocyte is presumably of autochthonous origin, though it may perhaps be derived from external sources. If the foreign substance originates within the organism it is either enterogenous or histogenetic. It does not seem to be due to a retention anomaly, as carbonemia and carbonoxydemia fail to reduce aniline dye stains (eosin-methylene blue; coryo red; bichloride scarlet — the latter being the one almost always used by Dr. Stern). If the substance in question were derived by resorption from the gastro-intestinal canal it could not become an almost permanent factor in the blood, as this would presuppose a long and uninterrupted absorption of the products of intestinal hyperfermentation and putrefaction, a condition rarely existing, and notably infrequent in diabetes. On this account we have to consider the erythrocytic foreign element as a product of abnormal cell and organ activity or disintegration. This foreign substance, whether originating from perverted plasmolytic or nucleolytic processes or from anomalies of internal secretions, may thus safely be classed among the toxic principles.

The plausibility of the entosystemic origin of the substance deserves some attention. A considerable number of authors have noted the appearance of diabetes in previously healthy individuals after they have come in contact with diabetics. The transmissibility of the affection therefore seems possible, although no convincing proof of this has as yet been adduced. One might surmise that the abnormal blood constituent represents the metabolic products of a specific bacterium, and that the potency of such a toxine gives rise to the glycosuric phenomenon. Whether this foreign element constitutes the underlying etiological factor of the affection, or whether it is but another of the metabolic products of the diabetic condition, cannot as yet be pronounced upon.

Dr. Stern then spoke of "diabetic deterioration," a condition which he said was first recognized by himself.[1]

The three clinical varieties of diabetes arising from distinct direct causes, he went on to say, seem to be but the consequence of one and the

[1] New York Medical Record, December 18, 1897.

same fundamental disturbance. They may be thus differentiated:

(1) The glycosuria disappears after complete or partial exclusion of carbohydrates. The excreted dextrose is due to deficient glycolysis.

(2) The glycosuria persists after complete exclusion of carbohydrates. The excreted glucose is due to proteolysis.

(3) With the continued excretion of dextrose larger amounts of nitrogen are egested than were introduced with the nutriment. The excreted dextrose is due to plasmolysis.

DR. H. D. CHAPIN spoke on

DIABETES IN CHILDREN.

The three most notable points in regard to the disease in childhood, he said, were the following: (1) It is extremely rare; (2) the most marked symptom is exceedingly rapid emaciation; (3) it is almost invariably fatal, and in a short time. He described 2 cases which he had seen in consultation. The first was that of a boy four years old who was taken with what was supposed to be an ordinary cold and afterwards treated for malaria. He grew steadily worse, rapidly wasting away, and an examination showed the urine to be loaded with sugar. Death ensued in three weeks from the onset of the disease. The other was a similar case in a boy of six years. The urine contained 5% of sugar, and the emaciation was even more rapid. For some time before death the child was in a semicomatose condition. In the hospitals with which he was connected, Dr. Chapin said that it was his routine practice to have his house staff make examinations of the urine of all patients. Sugar was almost never found, while albumin and traces of casts were very frequently met with in pneumonia, gastro-enteritis, and many other diseases. The mere presence of glycosuria was not sufficient to base a diagnosis of diabetes upon, and he had recently seen a child who, notwithstanding the presence of sugar in the urine for six weeks (according to the statement of the attending physician), continued bright and active, without any emaciation, and eventually made a complete recovery.

DR. PEARCE BAILEY read a paper on

THE NERVOUS SYSTEM IN DIABETES.

We are still in doubt, he said, as to the real pathogenesis of the disease, and as additional investigations have been made the case for the rôle of the nervous system in the matter of causation has been weakened rather than strengthened. Ever since the experiments of Bernard it has been known that glycosuria follows various irritations of the nervous system; but it is found that the condition is always transitory. If, on the other hand, the pancreas is completely extirpated, a glycosuria results which is permanent and progressively fatal. Traumatism is a very common cause of glycosuria. After 212 cases of head injuries this was found in 20, and of 24 cases of fracture of the vault and of 21 cases of fracture of the base of the skull, glycosuria resulted in 5 of each class. It is true that diabetes is not infrequently associated with nervous disease, especially conditions resulting from cerebral hemorrhage due to degeneration of the arteries. Such affections as sciatica and neuritis are sometimes also associated with diabetes, but these are liable to occur in connection with any wasting disease. Our conclusion then is that the primary cause of diabetes is not to be found in the central nervous system.

DR. S. SHERWELL read a paper on

CUTANEOUS COMPLICATIONS.

He mentioned the following, in the order of their frequency and importance:

(1) *Xeroderma.* — This is a functional variety, coming on rather suddenly and often associated with pruritus. The faucial appearances, which are peculiar and characteristic, not infrequently lead to the diagnosis of diabetes.

(2) *Pruritus.* — This is of a most severe and distressing character, and of itself should excite suspicion.

(3) *Eczematous manifestations.* — These may occur in any situation, but are most frequently found on the flexor surfaces and especially about the anus and genitals, and are characterized by the most intense itching. They are more efficiently treated by mild lotions of such agents as bichloride of mercury (1 to 1,000) and salicylic acid than by the ordinary unguents.

(4) *Furuncular and carbuncular manifestations.* — These also should excite suspicion of diabetes, and they require systemic treatment.

(5) *Erythematous manifestations.* — These sometimes result in such grave conditions as erysipelas and gangrene, especially in the lower extremities.

(6) *Bullous manifestations.*

(7) *Tumor formations.* — These are quite rare. The variety generally seen is xanthoma, the most frequent seat of which is the inner canthas of the upper eyelid. The other variety is a blastomycetic dermatitis, which has been described by Hyde, Montgomery, and Gilchrist of Baltimore.

Dr. N. J. HEPBURN read a paper on

OCULAR MANIFESTATIONS.

These, he said, are of two classes, (1) Those due to defective innervation, and (2) those due to defects in nutrition. Cataract is frequently met with in connection with diabetes, but it is doubtful whether it is not simply a concomitant, rather than due to the diabetic condition. Among the other serious affections liable to occur are optic neuritis and hemorrhage and detachment of the retina. Parenchamatous or pustular keratitis, when syphilis and tuberculosis can be excluded, should excite suspicion of diabetes. In brief, the eye affections most commonly associated with this disease are as follows: (1) Cataract; (2) recurring hordeolum, or sty; (3) paresis of accommodation; (4) keratitis.

DR. ROBERT T. MORRIS spoke on

DIABETES IN SURGERY.

He said that while until recently many cases for operation were forbidden to surgeons on account of the existence of this disease, at the present time but few such cases were excluded. In diabetes the blood, loaded with sugar, draws serum from the tissues, so that the latter become too dry. This hygroscopic action of the sugar, therefore, interferes with the repair of wounds. It is probable also that in this condition of affairs the alexines are not properly formed to meet the toxines. It is, consequently, of great importance that the surgeon should be especially careful in operating, for if infection once begins, it is very apt to be progressive. Diabetic cases, Dr. Morris said, were the only ones in which he took the precaution of wearing rubber gloves when operating. Another reason why diabetes interests the surgeon is because the sugar in the blood makes the serum an excellent culture medium. As to the use of anesthetics when this disease is present, it is best to avoid ether, for the reason that the latter, added to the effect of the sugar on the kidneys, may precipitate a nephritis. It is advisable, therefore, to begin with nitrous oxide gas and afterwards continue with chloroform, or, if practicable, with nitrous oxide gas and oxygen.

Transitory diabetes is often met with as the result of injuries. About one-half the cases of this occur in connection with head injuries. In many cases of traumatic glycosuria it is found that polyuria continues for a considerable time after the sugar has disappeared; which would seem to indicate that the functional disturbance of the liver probably terminates before that of the kidneys. After touching upon other points Dr. Morris referred, in conclusion, to a matter liable to come up in accident assurance cases. When a surgeon is asked, in a case where diabetes has been noted after an injury, whether the condition has been caused by the injury, he should be cautious in expressing a positive opinion, for it may be found that the patient was the subject of diabetes before the injury was met with.

DR. ABRAHAM MAYER read a paper on

THE TREATMENT OF DIABETES.

Until we have discovered the exact etiological factors of the disease, he said, our treatment must be one of symptoms. Among the objects of treatment were the elimination of sugar from the blood and urine, the maintenance of the general system, and the prevention of complications. The reader naturally devoted special attention to dietetic treatment. It was a great error, he thought, to exclude the carbohydrates entirely, except temporarily for diagnostic purposes. He gave descriptions of "rigid diet" and "mild diet," and said that many cases would do perfectly well on the latter. In placing a patient upon a course of restricted diet it was important to begin in a very gradual way, so that the system should become accustomed to the change.

With regard to medication, he had found opium, arsenic and bichloride of mercury the drugs of most service. Opium, which was of the greatest general use in controlling various annoying symptoms, should not be used continually, but interruptedly. It should be given in small doses (not more than $\frac{1}{8}$ a grain three times a day at first), and its constipating effect should be counteracted by cascara sagrada, or other laxative. The only two forms in which he had employed arsenic were Fowler's solution and bromide of arsenic. The latter was given in doses of from $\frac{1}{30}$ to $\frac{1}{10}$ of a grain, in much water, three times a day after meals. There were certain cases of diabetes, generally occurring in middle age, which were like a bacterial invasion or ptomaine poisoning. In these the bichloride of mercury had a certain, perhaps specific, value. The dose, at first small, should be increased to $\frac{1}{8}$ of a grain. Even if the sugar was not entirely eliminated, many patients could get along very comfortably for years. The diabetic's attention should be diverted as much as possible from himself, and he should be free from professional or business cares and other sources of worriment. He should wear warm clothing and avoid fatigue and all excesses. Massage and carbonic acid baths were often of great service, and visits to various health resorts, with the use of mineral waters to aid digestion, had a good effect. About 25% of diabetics died from phthisis.

DR. E. H. BARTLEY spoke on

GLYCOSURIA AND DIABETES MELLITUS IN RELATION TO LIFE INSURANCE.

After stating that this was a question of diagnosis and prognosis, he referred to the presence of sugar, in small quantity, in normal urine, and said this was a fact now pretty generally accepted. With the use of the ordinary tests this could not be detected, but under special tests it appeared in about one-third of the specimens of normal urine examined. Now when does a urine contain enough sugar to constitute what is generally known as glycosuria, and when does glycosuria become diabetes mellitus? Shall an applicant be absolutely rejected because he has a small amount of sugar in his urine? The rule should be that any case in which sugar is detected by the ordinary Fehling or Trommer test calls for a reexamination. He had never yet met with an instance in which a urine containing sugar did not reduce copper. Cases of real diabetes are met with, however, in which the urine contained no sugar at the time the examination was made, and it was conceivable that such cases might be passed by an examiner. An applicant could not be rejected on account of diabetes when an examination, made in the ordinary way, did not detect the presence of sugar. He knew of no way of making a diagnosis between glycosuria and diabetes mellitus.

He was in the habit of disregarding percentages entirely, and always insisted that the number of grains or grammes in twenty-four hours should be ascertained. The total solids could be readily obtained with sufficient accuracy, and in true diabetes the amount was always above 1,000 grains. In diabetes there is an excess of urea, while in

glycosuria the urea is not excessive. In life insurance examinations it was a good plan to keep the applicant for one hour, requesting him to pass his urine, at the beginning and end of this time. From the specimens thus obtained the amount passed in twenty-four hours could be estimated. The blood-staining tests for diabetes referred to had not come into general use, and the latest authorities had declared that they have no specific value. As to the most satisfactory method of detecting sugar in the urine, he could not agree that this was to be found in the fermentation test, for the reason that when no sugar was present, turpentine and other agents would ferment with yeast. No test was infallible, and it was therefore advisable to make use of several tests, especially in all doubtful cases. Personally he always employed three tests, namely, the bismuth, the indigo-carmine, and Trommer's, or Fehling's (with glycerine).

In order that a test should be entirely satisfactory it was requisite that preliminary testing should be resorted to. Creatinin was the substance most likely to interfere with the sugar test, and Allen's method was the one he was in the habit of using.

DR. CHAPIN said he should like to make an inquiry as to the significance of the presence in the urine of albumin in connection with sugar. He had met with a number of such cases. One of them was seen four years ago with a well-known consultant, who expressed the opinion that this conjunction was of fatal augury. Yet the patient in question was still living, and was at the present time in fairly good health.

DR. A. H. SMITH spoke of the remarkable frequency of diabetes among locomotive engineers, in whom, he had ascertained, the proportion of those affected with the disease was nearly five times as great as in the general average of individuals; and said that this was apparently due to the constant mental strain to which this class of men was subjected. In the same way the disease was very frequently met with among bank and railroad presidents and others in positions of similar responsibility. In the treatment of diabetes he thought one very important point was to relieve the patient of anxiety as much as possible and to divert his attention from his ailment.

DR. CROOK was inclined to attribute more importance to the rôle of the nervous system in the production of diabetes than had been admitted in the present discussion.

DR. STARK said, in reply to Dr. Chapin's inquiry, that in at least from one-fourth to one-third of all cases of diabetes some albumin was present, and that, as a rule, it had no special significance.

DR. MAYER said that the statistics in regard to the disease were more or less unsatisfactory. Many diabetics with phthisis entirely lost their sugar, and hence in the report of their deaths there might be no mention of diabetes. He did not believe that albuminuria was quite as common as Dr. Stark had represented; but when albuminuria was present in quantity it was quite a serious matter.

DR. BARTLEY said he had generally found that albumin appears late in the course of the disease, unless there had been some kidney trouble previous to the glycosuria. He always regarded it as indicating overwork, and a serious matter.

Recent Literature.

The Students' Manual of Venereal Diseases. By F. R. STURGIS, M.D., sometime Clinical Professor of Venereal Diseases in the Medical Department of the University of the City of New York; formerly one of the Visiting Surgeons to Charity Hospital, B. I., Dept. of Venereal; Member of the American Association of Genito-Urinary Surgeons, etc. Seventh edition. Revised and in part rewritten. By F. R. STURGIS, M.D., and FOLLEN CABOT, M.D., Instructor in Genito-Urinary and Venereal Diseases in the Cornell University Medical College; Genito-Urinary Surgeon to Bellevue Hospital, Out-patient's Department; Visiting Dermatologist to the New York City (Charity) Hospital; Lecturer on Venereal and Genito-Urinary Diseases in the University of Vermont. Philadelphia: P. Blakiston's Son & Co. 1901.

The first edition of this book appeared about twenty years ago. Since that time, although a number of similar manuals have been published, this one has exhausted six editions, and now the seventh edition appears, well revised, attractively printed and enlarged to 205 pages with a sufficiently good index. The book is divided into twelve chapters, two of which are devoted to a consideration of chancroid, seven to syphilis, and three to gonorrhea, as it manifests itself in both sexes. The book is what it represents itself to be —a manual for students—and considers the three venereal diseases in a condensed and almost schematic way, avoiding the discussion of all mooted questions. Medical students will doubtless receive this edition with the same favor which they accorded the others, but for the profession at large the book has little interest.

A Textbook of Diseases of the Nose and Throat. By D. BRADEN KYLE, M.D., Clinical Professor of Laryngology and Rhinology, Jefferson Medical College, etc. Second edition Philadelphia: W. B. Saunders & Co. 1900.

This does not differ from the first edition, which was reviewed in these columns a few months ago. The early appearance of a second edition shows that there are many who have found the book satisfactory.

BILL PROVIDING DISSECTING MATERIAL FOR BOSTON INSTITUTE OF OSTEOPATHY. — It is reported that a bill permitting the Boston Institute of Osteopathy to receive bodies for dissection has passed the State Senate by a vote of 17 to 10.

RESTRICTIVE MEDICAL LEGISLATION.

A matter which is likely to excite more and more interest and also to involve increasing difficulties is the rôle of the law in matters relating to health. As our knowledge of disease and its prophylaxis has grown, the tendency has been to enforce by law what experience has shown is for the good of the public health. This is particularly true of infectious and contagious diseases, in which our knowledge approaches nearest to certainty. There is now very little objection made on the part of people of intelligence in aiding Boards of Health and the authorities in discovering and reporting cases of disease of this type. This is wholly a matter of education, based on knowledge which any man of ordinary intelligence has no difficulty whatever in verifying. It is only among fanatics and extremists that systematic opposition is now made to regulations which a few years ago were generally looked on with suspicion. Inasmuch as the design of such laws is to protect the public, it is clear that the people's intelligent sympathy and co-operation must be enlisted before any material progress may be made. Compulsory vaccination has been found much more difficult of enforcement, simply because the people who must undergo the operation are not universally convinced of its efficiency. The arguments advanced in its favor, which are conclusive to the physician, do not appeal to the laity, as a body, with the perfectly inevitable result that the regulation is evaded, and the passage of laws rendered difficult and at times impossible. Another example in which still less progress has been made, has been the attempted prevention by law in certain western states of the residence of tuberculous persons within their borders, who have gone there in search of health. This legislation, so far as we know, has wholly failed. It could not be tolerated for any length of time either by the people or by the more enlightened physicians, either on moral or hygienic grounds.

By far the most extraordinary bit of legislation that has recently come to our notice is an apparently serious attempt in Minnesota to check the growth of mental disease by the enactment of a law making it illegal to marry without a physician's certificate of the soundness of mind of the contracting persons and of their parents and families before them. That such a law, if passed, will sooner or later meet with the opposition and defeat it deserves is unquestioned. In the present absolutely rudimentary state of our knowledge of this vague field of medicine, it is perfectly clear that the decision of the fitness of persons to marry in individual cases cannot be determined by a physician or any number of physicians with the slightest approach to justice. We are laboriously learning a little of the etiology of mental affections; the bugbear of heredity, though still sufficiently in evidence, is being subordinated as it has been in so many other affections, to the results of accurate study. The influence of infections, of overwork, of intoxications, of chronic disease of other organs, and many other agencies are being taken into account, with the result that some glimmering of light is being thrown into the dark places. It needs no detailed argument to realize that we are very far removed from a knowledge which will permit of dogmatism in any given case, especially when the decision involves a matter of such vital social concern.

After writing somewhat tentatively of the proposed law, the *Medical News* in a recent editorial says:

> If there were any way of shortening the effect of time and presenting human experience to individuals in a rapid series of vivid consecutive pictures of cause and effect, the people would be the first to call out for laws to protect them. No one questions the laws that prevent leprous, cholera and plague patients from entering our communities and mingling with the people, because the fatal consequences follow so quickly that the people learn their object lesson with revolting horror. But could they see in as many days, as it takes years, the development of insanity, the slow, pitiful suffering of the unfortunates and the horror and anxiety and heart-break of their friends in the cases that spring with the regularity of statistics, in the children and grandchildren and great-grandchildren of a person who has insanity in his family, if these could be presented to the people as vividly as the physician sees them, there could be no more telling object lesson, and one would as readily share his marriage-bed with a leper or a plague patient as with a person directly tainted with insanity.

This is neither scientific nor cogent argument. To contrast the question at issue with leprosy, cholera and plague, should not influence a sober-minded person in the least, and to make such comparisons surely does not advance the cause inasmuch as the conditions are not comparable. The

Philadelphia Medical Journal commenting on the same subject writes as follows:

This new and preposterous law would make it illegal to marry without a physician's certificate as to the mental soundness of the contracting parties as well as of the families of both of them. It is difficult to know where to begin to criticise such a law. The crusade against cigarettes is as the wisdom of Solon compared with it. We do not stop for a moment to condemn it on ethical and humane grounds; it condemns itself there. To say that any person who had had a parent, a grandparent, or a brother or sister, the victim at some time of an attack of insanity, or epilepsy, should be debarred from marriage by the certificate of a physician, is too wantonly barbarous and too crudely unscientific to need to be criticised at all. We simply point to the utter impracticability of such a law on the ground that the proof of insanity in a family is the hardest to establish and the easiest to conceal of any kind of proof. All psychiatrists know this from almost daily experience. Such a law apparently places the happiness of two individuals for life on the scientific acumen and psychiatrical skill of the average practitioner of medicine in Minnesota, or leaves the law itself to die a natural death from the inability or unwillingness of a doctor to step in and forbid the banns in the case of some young man or young woman whose mother may have had puerperal insanity, or whose grandfather may have had senile dementia, or whose wayward brother may have just recently died of general paresis. The general sense of mankind will condemn such laws as it has condemned them since the time of the Spartans.

For our own part we are convinced that such a law is neither wise nor just nor capable of successful enactment. The problem is far too involved to be treated in this off-hand manner. Absolutely desirable as it is to improve the human stock by every legitimate means, we should not for a moment forget that far too much of late has been said of degeneracy and far too little of the possibility of regeneracy, and also that in this matter beyond all others the education of the masses must play a leading part in the eradication of the weak, and the perpetuation of the strong. Legislation may, for the present, far better devote itself to more practicable problems of health, of which there are enough and to spare.

THE EPIDEMIC OF TYPHOID FEVER AT NEW HAVEN, CONN.

WE are told so often that typhoid fever is a preventable disease that we had almost come to regard the statement as a fact. Undoubtedly it is preventable, provided only the acknowledged precautions are adopted by everyone at all times to prevent its dissemination. As a matter of experience, however, this consummation is hardly to be anticipated until human nature has attained a degree of perfection of which it now falls far short. The laity must, somehow or other, be trained to a realization of the possible consequences of their carelessness in neglecting the requirements of sanitation. With the most scrupulous care accidents may no doubt happen, but this should be an incentive to renewed precaution rather than to increased carelessness.

New Haven is now the centre of a very considerable epidemic of typhoid, the source of which has been discovered, but too late to prevent the appearance of several hundred cases of the disease. It is also of interest that the disease has found its victims in one of the better residence portions of the city, in the immediate neighborhood of the Yale University buildings. Fortunately the students have, as yet, been practically free from infection, said to be due to the fact that they are not accustomed to drink the city water. It is, however, natural that parents should be solicitous under the circumstances regarding the return of their sons to college at the opening of the spring term. Naturally precautions have been taken, and notices posted, warning the students against drinking city water unless boiled, and also, it is said, against eating uncooked vegetables. No doubt such precautions will prove efficacious, but the fact remains that a very great menace to health will exist for a considerable time, with so widespread an epidemic as this appears to be.

We have no reason to suppose that the New Haven Board of Health has been in any way deficient in its duty, nor have we any authoritative knowledge as to where the blame lies. But that some carelessness has existed somewhere, which might have been averted is self-evident, and it is at least to be hoped and expected, that a similar accident will not soon happen again. Each unfortunate experience of this sort brings with it the consolation, small though it may be, that the knowledge gained may be put to practical use by an increasingly rigid prophylaxis in the future.

THE PROPOSED BACK BAY WATER PARK AND THE HEALTH OF BOSTON.

MALARIA, like various other diseases the fear of which has been proportionate to our ignorance of their cause, is likely to be regarded with much greater equanimity in the future than it has been in the past. Owing to the investigations of the last few years, we are now in a position to say with almost complete assurance under what conditions it will appear. The proposition to improve the Charles River basin by constructing a collapsible dam has met with a certain opposition from various sources, and among others from a few persons who have regarded such a collection of water, uninfluenced by the tides, as a menace to the health of the city, and particu-

larly of the Back Bay region, owing to the probability of the introduction of malaria. However much weight this argument may have had several years ago, it has completely lost its force since the discovery that malaria depends for its dissemination upon the presence and activity of a certain species of mosquito. In the recently promulgated pamphlet sent to various citizens of Boston advocating the consideration of a water park, was an appended statement by Dr. Richard C. Cabot, in which, no doubt after a mature consideration of the question, he states his belief that the malarial mosquito cannot breed in such a basin as the one proposed would be, and that, therefore, malaria will not be introduced by the suggested improvement. If this be the fact, and there can be no doubt that it is a matter which, with our present knowledge, an expert may definitely decide, the case against the water park falls so far as the question of public health is concerned. Other arguments against the proposition there may be; they do not concern us here, but of this we may be practically certain, that the danger from malaria, about which so much has been said, does not exist.

This is unquestionably a most important point to establish. Were the other alternative likely or possible, we can easily see in it an argument of much weight against the suggested improvement. As the matter now stands, however, the unadvisability of the park must rest on totally different grounds than those of public health.

MEDICAL NOTES.

The St. Paul Meeting of the American Medical Association and Yellowstone Park. — Arrangements have been completed for an excursion of the members of the American Medical Association to Yellowstone Park at the coming meeting. The committee of arrangements has succeeded in having the park opened a week earlier than usual in order to accommodate the Association. A special train will be run from St. Paul to the Yellowstone Park. Further announcements will be made later.

Leprosy on Teneriffe Island. — The existence of about 200 lepers on the island of Teneriffe, Canary Islands, has been officially reported at Washington by the United States Consul. At Santa Cruz de Teneriffe, the capital, there are 22 lepers, 15 of whom are men, and there are also some children. There are in addition living at the same place about 200 people. Officially it is not recognized that leprosy exists on these islands.

Officers of Pennsylvania Society for the Prevention of Tuberculosis. — At the annual meeting of the Pennsylvania Society for the Prevention of Tuberculosis held on April 10, 1901, at the Academy of Natural Sciences, Logan Square, Philadelphia, Dr. Guy Hinsdale was elected president, and Alex. Heron Davisson, secretary. Thirty-one thousand copies of the society's publications were issued in the past year.

Increased Session of New Orleans Polyclinic. — The session of the New Orleans Polyclinic will be continued until May 31st instead of May 11th as previously announced.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 17, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 48, scarlatina 17, measles 85, typhoid fever 9.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending April 13th was 234, as against 269 the corresponding week last year, showing a decrease of 35 deaths, and making the death rate for the week 21.7. The deaths from consumption were 33, pneumonia 38, whooping cough 1, heart disease 25, bronchitis 9, marasmus 2. There were 13 deaths from violent causes. The number of children who died under one year was 36; under five years 57. Persons more than sixty years 52; deaths in public institutions 63.

Board of Health Police. — Two policemen have been assigned to assist the Board of Health in maintaining cleanliness and in taking care of persons attacked by contagious diseases. The Board of Health has always obtained such assistance as it needed from the Police Department, by making a request for it each time. The present arrangement will do away with this formality.

Meeting of Carney Hospital Alumni. — The thirteenth annual dinner of the Carney Hospital Alumni Association was held April 11th in Boston. Dr. M. E. Keen, of Manchester, N. H., presided, and the following officers were elected for the ensuing year: John M. Hastings, M.D., president; J. Shepard May, M.D., vice-president; E. P. Hatch, M.D., secretary and treasurer.

A Centenarian. — Michael Foley, said to have been the oldest man in Connecticut, has recently died in Versailles at the reputed age of one hundred and one. Up to a few weeks ago he is said to have been able to do farm work.

Typhoid Fever in New Haven, Conn. — Up to April 15th, the total number of reported cases of typhoid fever in New Haven was 350.

NEW YORK.

RESPONSIBILITY FOR ELEVATOR ACCIDENTS. — Another decision recently given by the Court of Appeals, in which it differs from and overrules the Appellate Division, is one in reference to the extent of the responsibility of owners of office buildings for elevator accidents. About a year ago the Appellate Division unanimously affirmed judgment given in favor of the administratrix of a tenant in an office building who had brought suit for damages for the death of her husband by an accident of this character. The trial judge charged the jury that the owner was bound to use the utmost care as to any defect which might be liable to occasion great danger or loss of life, and he was in that respect subject to the same rule that applied to a railroad company in regard to its roadbed, engines and similar equipment. The Court of Appeals, on appeal, now holds that the owner of the building, in maintaining and operating a passenger elevator, is bound to use a degree of care which is reasonable in view of the dangerous character of the service. He is not, however, bound to exercise the utmost human care and foresight to guard against danger. The latter rule, which is applicable to railroads, where, for a consideration, there is a contract to carry safely, does not apply to the management of an elevator in an office building. The prevailing opinion, which was by Judge Cullen, was concurred in by Judges Vann, Werner and Gray; Judges Bartlett and Martin dissented. "In these days of lofty buildings," Judge Bartlett said, "and the annual transportation of millions of passengers in elevators by interested owners, who could not otherwise rent their property, public policy requires them to exercise the same degree of care as is imposed on common carriers."

DECISION REGARDING NEGLIGENCE OF RAILROADS. — A decision has been rendered by the Court of Appeals, reversing unanimous decisions of the Appellate Division of the Supreme Court, which settles some mooted questions in reference to contributory negligence in the case of persons injured or killed while attempting to cross railroad tracks in cities. The details of the case on trial are somewhat complicated. Judge Vann, who gives the unanimous opinion, holds that a railroad company which runs a locomotive rapidly in the night upon a public street in a populous city, crossing other streets at grade, with no gate or flagman to protect the public, and without taking any precaution to warn by bell, whistle, or otherwise, except by means of its headlight, may properly be found guilty of neglecting its duty to operate its cars with the care and caution required by the circumstances.

MORTALITY STATISTICS IN MARCH. — The general mortality in March represented an annual death rate of 21.39, against 25.56 in February. In March of last year, the death rate was much higher; the figure then being 25.56. In March of the present year, as compared with February, the weekly average of deaths from diphtheria and croup increased from 40.75 to 52; from scarlet fever, from 27 to 34.75; from pneumonia, from 158.5 to 201; from phthisis, from 173.5 to 179.75; from bronchitis, from 41.5 to 49.5; from cancer, from 44.25 to 48.5, and from diseases of the urinary system, from 123.75 to 129.25. On the other hand, the weekly average of deaths from influenza decreased from 51.75 to 27; while the mortality from measles, whooping cough and typhoid fever (very low in all these affections) continued about the same.

SUIT AGAINST A HOSPITAL PHYSICIAN. — A suit is now in the courts which is of much interest to the profession. Peter Ryan, a former charity patient in the City Hospital on Blackwell's Island, has brought an action for $25,000 against Dr. Edward Sprague Peck, one of the most eminent ophthalmologists in New York and a surgeon to the hospital, for the loss of his sight through an operation for cataract. The city, while not made a party to the suit, is defending the action on the ground that Dr. Peck was in its service and received no compensation. It is claimed by the defence that the loss of sight was due to the patient's own carelessness.

A GIFT TO THE LOOMIS SANITARIUM. — J. Pierpont Morgan has purchased, for $40,000, the plant of the Liberty Electric Light and Power Company, which furnishes the electric light for the village of Liberty, Sullivan County, and presented it to the Loomis Sanitarium for Consumptives, situated at that place. The gift is regarded of much importance to the sanitarium, as it will not only greatly reduce its expenses for lighting, but also provide it with a permanent source of considerable income. The administration building, costing $80,000, was a previous gift of Mr. Morgan, who is one of the incorporators and trustees of the institution.

INFLUENCE OF SMALLPOX ON INFLUENZA. — Dr. F. C. Gram, Registrar of the Buffalo Health Department, announces as the result of recent observations, that smallpox exerts an influence on influenza apparently not hitherto noticed. The health authorities have just concluded a general vaccination, the work being done at a time when the city was suffering from a very severe epidemic of influenza. The reports show that simultaneously with the appearance of manifestations of vaccinia in influenza patients the symptoms of the latter disease disappeared.

A NEW CHRISTIAN SCIENCE CHURCH AND ACCESSORIES.—The Christian Scientists who recently dedicated an expensive new building on Central Park, West (the first "church" of the sect to be erected in the city), are not lacking in an eye to business. Among its appointments are a considerable number of consultation rooms, with private entrances from the street, which are to be rented out to "practitioners" for office work. The first and second "readers," Mrs. Lathrop and her son, are said to be given their offices rent free.

SMALLPOX IN NEW YORK.—Smallpox is not decreasing in New York. In November 35 cases were reported; in December, 68; in January, 78; in February, 142 and in March, 194. In January the average number of cases per day was less than three; in February it was four; in March, six, and in the first eleven days of April, seven. While, however, there were more cases in March than in February, the weekly average of deaths from the disease was exactly the same, namely, eight.

AMENDMENT OF PUBLIC HEALTH LAW REGARDING DENTAL SOCIETIES.—Governor Odell has signed a bill amending the public health law relative to the incorporation of dental societies permitting men who studied under private preceptors to take the state examinations in dentistry, provided their certificate of study was filed prior to July, 1895, and requiring dental students to pursue a three years' course in a registered dental school.

RE-ELECTION OF DR. ENOCH V. STODDARD.—At the meeting of the State Board of Charities held at Albany on April 10th, Dr. Enoch V. Stoddard, of Rochester, was unanimously re-elected vice-president for the eighth consecutive time.

A SUMMER HOME FOR NURSES.—The property known as the Grace Church Fresh Air Home, at Far Rockaway, has been purchased by the wife of Dr. Walter B. James for a summer home for trained nurses.

SMALLPOX IN ALBANY.—A serious outbreak of smallpox is reported at the Lathrop Memorial Home, Albany, a charitable institution situated in a populous residence district of the city.

BILLS OF ROOSEVELT TENEMENT HOUSE COMMISSION.

AFTER a public hearing on the measures, on April 10th, Governor Odell, on April 12th, signed the four bills, recently passed by the Legislature, which were framed by the Roosevelt Tenement House Commission. In doing so he filed with the bill providing for the manner of the construction of tenement houses a memorandum recommending some supplemental legislation. The principal reforms that the new laws will bring about will be in brief, as stated by Mr. De Forest, Chairman of the Commission, more air and light, the doing away with dark interior rooms and cellar rooms, proper sanitary appliances for every family, proper protection against fire, and a proper enforcement of the laws regarding tenement houses. This will be accomplished by the new Tenement House Department provided for by one of the bills. The head of this, who is to be called the Tenement House Commissioner, will be held personally responsible for any violations of the laws. He is to be appointed by the mayor and to receive an annual salary of $7,500. He will have power to appoint and remove at will one or more Deputy Commissioners, at an annual salary not to exceed $5,000, and will also have power to appoint all the employees in the department and to fix their salaries. In the department will be included a building bureau, an inspection bureau, and a bureau of records, and the Commissioner will have power to form other bureaus, if deemed advisable. The provisions against using apartments in tenement houses for immoral purposes are very severe.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 6, 1901.

CITIES.	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Newburyport	14,478	3	—	—	—	—	—	—
Melrose	12,962	—	—	—	—	—	—	—

Deaths reported 2,263; under five years of age 677; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 514, acute lung diseases 403, consumption 248, diphtheria and croup 72, diarrheal diseases 53, scarlet fever 61, influenza 7, ty-

phoid fever 22, whooping cough 10, measles 8, cerebro-spinal meningitis 5, smallpox, 8.

From whooping cough, New York, 3, Pittsburg, 3, Boston, Lowell, Quincy and Chicopee, 1 each. From cerebro-spinal meningitis, New York, 3, Baltimore, 1, and Salem, 1. From scarlet fever, New York, 44, Boston, 9, New Bedford, 3, Medford, 2, Springfield, Brockton and Hyde Park, 1 each. From typhoid fever, New York, 11, Pittsburg, 4, Baltimore, 3, Lowell, Lawrence, Haverhill and Clinton, 1 each. From measles, New York, 6, Boston 2. From smallpox, New York, 8.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending March 23d, the death rate was 18.4. Deaths reported, 4,162; acute diseases of the respiratory organs (London), 332, whooping cough 122, diphtheria 53, measles 93, fever, 22, diarrhœa, 38, scarlet fever, 27.

The death rate ranged from 10.7, in Halifax, to 23.6, in Liverpool; Birkenhead, 20.1, Birmingham, 19.3, Blackburn, 22.1, Bolton, 20.4, Bradford, 15.9, Brighton, 12.9, Bristol, 21.2, Burnley, 14.7, Cardiff, 14.4, Croydon, 15.5, Derby, 17.1, Gateshead, 21.4, Huddersfield, 22.7, Hull, 21.2,, Leeds, 19.4, Leicester, 13.5, London, 17.8, Manchester, 23.4, Newcastle-on-Tyne, 19.4, Norwich, 18.8, Nottingham, 15.7, Oldham, 13.0, Plymouth, 17.1, Portsmouth, 25.7, Preston, 23.0, Salford, 20.8, Sheffield, 21.2, Sunderland, 18.9, Swansea, 21.9, West Ham, 11.4, Wolverhampton, 12.1.

METEOROLOGICAL RECORD.

For the week ending April 6th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Date.	Barometer	Thermometer.			Relative humidity			Direction of wind.		Velocity of Wind.		We'th'r *		Rainfall in inches.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Obstetrics and Diseases of Women will meet in Sprague Hall, Boston Medical Library Building, 8 The Fenway, Wednesday, April 24, 1901, at 8 P.M.

Papers: Dr. F. B. Lund, "A Case of Melanotic Sarcoma Simulating Urethal Caruncle"; Dr. C. G. Cumston, "Lesions of the Bladder During Abdominal and Vaginal Hysterectomy."

Discussion by Drs. Stevens, Ryder, Kingman, Garceau, Coggeshall, Twombly, Hare and Breck.

W. H. GRANT, Secretary.

ASSOCIATION OF AMERICAN MEDICAL COLLEGES. — The next regular meeting of this Association will be held at the Hotel Ryan, St. Paul, Minn., June 3, 1901.

RESIGNATION.

DR. AUGUSTUS P. CLARKE, dean and professor of gynecology at the College of Physicians and Surgeons since 1893, has resigned.

RECENT DEATHS.

DR. WILLIAM JAY YOUMANS, for many years the editor of the *Popular Science Monthly*, died at his home in Mount Vernon, Westchester County, New York, on April 11th, at the age of sixty-two. His death was due to typhoid fever. Dr. Youmans was born near Saratoga on October 14, 1838. He studied chemistry at Columbia College, New York, and at the Sheffield Scientific School of Yale, and was graduated from the Medical Department of the University of the City of New York in 1865. In 1872, in connection with his brother, Professor Edward Livingston Youmans, of Columbia, he established the *Popular Science Monthly*, published by the Appletons, and after his brother's death was its sole editor until a year ago, when the publishers became involved in financial difficulties. Two of his children are physicians.

BOOKS AND PAMPHLETS RECEIVED.

An Extraordinary Case of Aortic Aneurysm. By Carl Beck, M.D., of New York. Reprint. Illustrated. 1899.

REMARKS ON ANESTHESIA — GENERAL, LOCAL AND SPINAL.[1]

BY MAURICE H. RICHARDSON, M.D., BOSTON.

THE introduction of spinal cocainization excites renewed interest in the general subject of anesthesia. Every surgeon of experience deplores the occasional accidents and disadvantages of general anesthesia, and would welcome any method which, while avoiding them, adds no other and perhaps greater risks. In attending the great clinics of this country I have been impressed by the care and anxiety of the surgeon in regard to the anesthesia of his patient. This extreme solicitude has been expressed perhaps more by those of wide than by those of limited experience. The reason is not far to seek. Few men can hope to spend many years without meeting some of the accidents of anesthesia. Immunity from them for a few months or years, perhaps for many years, may beget a false security and encourage careless methods. In most hospital clinics the anesthetic is given by the youngest interne, and his administration of it, supervised habitually and almost unconsciously by the surgeon himself, is ordinarily safe enough. When emergencies of operation arise, however, when every faculty of the surgeon is devoted to the operation itself, when, perhaps, the patient's condition is alarming, when therefore, especial care and experience in anesthesia are demanded, and when, more than ever, the surgeon should see that great caution is used; — at that time of all others the etherizer may be left to himself.

I recall an emergency of the most formidable nature which suddenly arose during an operation for hernia in a man of sixty. Something aroused my suspicions, and I repeatedly asked the etherizer if all was well. He said "Yes" every time. I finally left the operation to see for myself. The patient survived only by the merest chance after tracheotomy and prolonged efforts at clearing the trachea below the tube. Respiration was seriously impeded in the throat; then completely obstructed there; no effort of mine could give access of air to the lungs. Tracheotomy gave only temporary relief: the trouble was lower down. Finally, with great difficulty, he was brought to life, and the operation was completed.

In private practice, especially in these abdominal emergencies in which great caution is necessary, the anesthetic may be given by a nurse, by a member of the family, or by a physician who perhaps has had little experience and who does not wish to take the responsibility of it, but is obliged to do so. Doubtless under these circumstances the patient is really safer under anesthesia than when an overconfident physician gives it, for the surgeon always keeps one eye on his patient and one on his operation. Indeed, so deeply is the surgeon impressed by the responsibilites of the anesthetic, that he can hardly hope ever to yield even to a professional anesthetist that full confidence which will enable him to devote his whole attention to the operation. It is but natural that he should feel so, for upon him, and him alone, will fall the responsibility of death from the anesthetic.

It is not my intention to go into the dangers of etherization, — for by general anesthesia I mean etherization. Suffice it to say that I have never had or seen a death from ether itself — a death, for example, under anesthesia for a trivial operation. I recall one death on the table during operation, the case of a very stout woman, with general peritonitis resulting from rupture of the uterus. The patient strangled in her own vomit, in spite of the surgeon's efforts to clear the trachea. Another patient, years ago, a young girl with empyema, died suddenly just as the anesthesia was complete. The whole left pleural cavity was filled with pus, the left lung being compressed into a small mass no larger than the hand. I was to assist in this operation. A patient of my own, seriously injured by an explosion of dynamite, died soon after the repair of a lacerated hand. The medical examiner made a careful examination, and reported the death to be owing to other causes than the anesthetic.

These deaths — the two coincident with the administration of ether, and the third from strangulation in a patient too feeble to swallow or to clear her throat — are the only ones which I have seen or had in a very large number of etherizations. They were all cases of serious disease or extensive injury, and death could not be fairly attributed to simple anesthesia.

There have, perhaps, been deaths due indirectly to ether, but their number is extremely small. Those owing to suppression of urine and to inhalation pneumonia are the only ones in which ether may have been an important factor. It is not clear that ether alone was responsible for them. In genito-urinary cases, particularly, suppression of urine may occur, and does occur, as the direct result of the operation itself, especially in cases of ascending infection. When a patient dies with suppression of urine after a double ovariotomy and a combined vaginal and abdominal hysterectomy, or after a cholecystotomy, or after a nephrectomy, it is an unwarrantable assumption that death was owing to the ether and not to the operation. Such an assumption is to accept the lesser, not the greater constitutional disturbance, and is against common sense. A death from pneumonia after ether is always attributed to the anesthetic, though the vast majority of pneumonias occur spontaneously. It seems absurd to say that a pneumonia developing three weeks after operation is owing to the anesthetic. Only pneumonia or bronchitis beginning directly after recovery from the anesthetic may fairly be said to be owing to that anesthetic.

The dangers of etherization are, in my opinion, trivial. I believe that the subcutaneous use of cocaine, especially in extensive dissections, will be found to be much more hazardous. The safety of

[1] Read before the Obstetrical Society of Boston, December 18, 1900.

ether depends upon the individual. If he is carefully studied the chief dangers will be avoided, for contra-indications to the use of ether will have been discovered. Healthy subjects, well prepared, are not injured by etherization in a large enough ratio of cases to justify discussion. Most experienced surgeons probably can say with truth that they never have lost a patient after operation under complete anesthesia for hemorrhoids, urethral stricture, castration, ventral fixation, simple ovariotomy, appendicitis in the interval, minor amputations, amputations of the breast, dissections of the axilla, dissections of the neck, removal of fatty and other benign tumors, examinations for diagnosis, and the like. If surgeons have lost a case here and there, it has been from causes other than the anesthetic.

I was taught by Dr. Bigelow the principles of etherization, and I have always followed them. Chief among these principles was the importance of careful administration and of attention to the warnings of danger. I have come to regard etherization, carefully carried out by one who understands it, as without danger to healthy individuals. Accidents come from disregard of danger signals, and from overetherization — not from the intrinsic dangers of the drug carefully given. I have been annoyed to see the overconfidence, the carelessness and the ignorance with which ether is generally given — on the ground that it is perfectly safe. It is not safe when no care is deemed necessary; it is is as safe as anything can be in surgery when carefully and intelligently administered to healthy subjects. It has dangers inseparable from its use in certain conditions of habit, physique, disease and idiosyncrasy.

General anesthesia is undesirable under certain conditions; it is strongly contra-indicated under some. Under some its undesirability is simply a matter of dread on the part of the patient.

Local anesthesia may be desirable or imperative, according to the circumstances. When nothing in the patient's condition forbids general anesthesia, that method is preferable for major operations. For minor operations, the local injection of cocaine, or other local anesthetic, is perfectly satisfactory. Spinal anesthesia, or local anesthesia by subcutaneous injections over considerable areas, may be considered in patients who are willing to take the possible risk because of their abnormal dread of a general anesthetic. Few patients, however, would be willing to run an unknown and serious risk owing to dread of a known and safe method, were the facts of the case fairly presented to them. They can hardly be advised to submit to spinal cocainization by those who look upon that means as of doubtful safety — to say the least. If willing, in spite of possible dangers, to risk spinal cocainization for an imperative operation, they would seem to have a right to try it.

The only justification for the use of extensive local and of spinal anesthesia lies in diminished risk to the patient. There are enough conditions in which the risks of general anesthesia are great, to provide a wide field for anesthesia. The most important are the abdominal diseases or conditions which endanger the patient's life by regurgitations into the throat during profound anesthesia. This danger is a real one, and is present whenever the patient is unable to swallow or to clear his throat. I have seen many patients die in the natural course of the disease from sudden flooding of throat and air passages in advanced general peritonitis with great distention and full stomach, when they were too feeble to clear either the throat or the air passages. Such a termination of general peritonitis or of intestinal obstruction is not uncommon. To subject a feeble patient to complete unconsciousness when his stomach and upper intestines are distended with thin fluid contents, is to invite disaster. Even when he is in good strength, the dangers at this time are great. No operation can cause greater anxiety than that undertaken for general peritonitis and for intestinal obstructions generally. When it is remembered that a large proportion of acute abdominal cases are attended by distention, the importance of this point is evident. Even if the patient survives the operation, there is always danger of an inhalation pneumonia or of a bronchitis. Indeed, it is safe to say that most post-operative pneumonias are owing to regurgitation of stomach contents and contamination of the air passages.

A similar danger is always present when emergency operations are performed upon patients with full stomachs. Many of the hospital cases are of this class. Railroad accidents, gunshot wounds, stabs, and the like, may demand operation soon after a full meal. Many of the sudden deaths during operations are owing to the inhalation of masses of undigested food, large enough to plug completely the pharynx or the trachea. Several accidents of this kind have occurred in this community, and doubtless may have occurred without the truth being known. In some instances a patient, previously warned not to eat anything for at least six hours before operation, has been known to take food without the knowledge of either his family, nurse or surgeon. Such extreme care is necessary in general anesthesia under these circumstances that the employment of local or spinal would seem justifiable.

When the heart, lungs, or kidneys, are seriously diseased, the selection of an anesthetic may present great difficulties. Heart disease, for instance, is usually regarded — among the laity at least — as a contra-indication to general anesthesia. My own experience is quite the opposite. I have operated for strangulated hernia, for example, in a case of acute puerperal endocarditis in which the patient's pulse was 210. The operation was of course brief, but the convalescence was satisfactory. I have yet to see the least sign of danger in the complete anesthesia of patients with cardiac disease.

The chief anxieties, in etherization at least, have come from disease of the lungs. I once assisted, or was about to assist, at an operation for empyema, when the patient, nearly etherized, sud-

denly died. How much the ether had to do with this unfortunate end cannot be told. It was undoubtedly the exciting cause in this case. Yet it would be absurd to say that death would have resulted had both lungs been normal. Since this experience I have always used especial care in etherizing patients with empyema. In a few cases I have used chloroform instead of ether, though I am entirely unconvinced that chloroform has any advantages over ether. In several desperate cases I have injected cocaine into the intercostal spaces above and below a rib before resecting and draining. Some of the patients have been in the most serious condition, with the pulse ranging between 180 and 200, and the operation has been accomplished in less than two minutes. Even in these desperate cases, the anesthesia, whether general of local, has been well borne.

The chief anxiety in etherizations generally has always been from changes in the respiration. I am inclined to think that this anxiety is seldom justified by the facts — at least seldom justified by any unfavorable results. Doubtless the very fact that abnormal respiration is feared, and that when its slightest symptoms are observed the ether is taken off, explains the favorable issue. With increased experience, irregularities and abnormalities of respiration in one's practice become less and less frequent; they occur in the hands of the fresh interne and inexperienced etherizer. Twice during a recent service I was obliged to leave the operation and to resort to artificial respiration. Both patients were strong and healthy males, one of early youth and one of middle age. The operations were in themselves slight — one a circumcision, the other a sinus curettage. Regular respiration ceased in both until the patient became cyanotic. How long they would have gone without drawing a breath themselves cannot be said. The aspect was too alarming to allow one to satisfy his curiosity on that point, for the patients made not the least effort to breathe. Their faces were darkly cyanotic and the pupils widely dilated. The air passages were perfectly free. There was simply failure on the part of the respiratory centres to respond to the evident call for oxygen. The hearts were pumping vigorously. Under artificial respiration continued for a minute or two the patients began to breathe naturally. I am convinced that patients under such circumstances will themselves resume respiration, though I have never dared to put the question to the proof. This form of unnatural respiration is not infrequent in the early stages of anesthesia, when it is a symptom of little moment. Failure to breathe is the result of the enforced respiration so often ordered by the etherizer. In response to frequent commands of "Take a long, deep breath," the patient's blood gets overoxygenated, and he can go a long time without breathing. The etherizer need feel no anxiety from this form of abnormal respiration. By taking quickly say forty to sixty deep inspirations, the diver can stay under water for some time. I have, for instance, remained under water without discomfort for two minutes and ten seconds after thus overaerating the blood. This would seem to the surgeon an interminable period, if his patient should make no effort to breathe.

When the patient fails to breathe during complete anesthesia it is a different matter, and artificial respiration must be practised. It is fortunate — and in this fact lies the great safety of ether — that the patient, with healthy lungs at least, always responds to artificial respiration.

The dangers of regurgitation from a full stomach in intestinal obstruction and in general peritonitis, or in both diseases combined, cannot be met by washing out the stomach beforehand, because regurgitation from the upper intestine refills the stomach by the time etherization is complete. I regard this danger as excessive, and as a full justification for local anesthesia or spinal injections. Whatever the dangers of the latter method, they do not seem likely to be as great as the danger of complete unconsciousness.

Local anesthesia in advanced general peritonitis and obstruction — distention has worked well in the few cases in which I have tried it. I have, for instance, drained a general peritonitis through a median incision made under cocaine, and have continued the irrigation for hours afterwards. I have removed the appendix under the same anesthesia in an apparently hopeless general peritonitis. The patient, indeed, instead of dying in a few hours, as he would have done, perhaps, had ether been used, lived several days, and for many hours gave hope of eventual recovery. On the other hand, a girl, almost moribund with general peritonitis, supposed to be of appendicular origin, lived a month after drainage of the pancreas for an acute hemorrhagic pancreatitis. Her condition was so desperate that cocaine was proposed. Chloroform was used, however, and anesthesia was complete.

The dangers of profound anesthesia in these cases are hard to overestimate, and yet anesthesia profound enough to ensure against vomiting, seems safer than keeping the patient on the verge of unconsciousness, etherized too much for swallowing and clearing his trachea, but not enough to prevent vomiting. When a patient fills mouth, nose and throat with the thin black vomitus of general peritonitis, and when after swabbing out as thoroughly as possible, his respiration is wheezy, his color and pulse bad, he should be allowed to come out of the ether enough to swallow and to clear his throat, no matter at what stage the operation may be, for these symptoms mean impending death. Under such circumstances the dangers of spinal anesthesia, however uncertain they may be, are the immediate ones from the general absorption of cocaine and its local effects upon the spinal contents; and they are not to be compared in their possible grave effects, as far as is known, with those of profound general anesthesia.

Local anesthesia is to be preferred for all trivial operations in regions where it can be thoroughly applied. The dangers of subcutaneous injections seem slight, if care is exercised in the introduction of the anesthetic under the skin, and if a

dilute solution is used. I have followed this method in all minor surgery, and at all ages except infancy. I use a 1% solution under the skin, slowly injected through an area first anesthetized with ethyl chloride. I have yet to see the least unpleasant or alarming symptom. By trivial operations I mean the removal of small tumors, aspirations, amputations of fingers and toes, small plastics, and the like.

Local anesthesia for operations like appendectomy, the radical cure of hernia, excisions of elbow, amputations of arm or leg, seems to me far from advantageous as compared with ether. I have used local injections of 1% solutions of cocaine, in the radical cure of hernia, and in acute appendicitis (the case already mentioned). The dissection proceeded painlessly until the peritoneum was reached. In the hernia the outcry was so great when the sac was reached that I was obliged to use ether. In the appendectomy, manipulations of the appendix and the meso-appendix caused excessive pain. I completed the operation, nevertheless, without general anesthesia. Wide experience in extensive subcutaneous local anesthesia in the robust is necessary before it will seem as safe and satisfactory as general.

In very feeble patients the selection of method presents great difficulties. The effect of ether in some is beneficial, the pulse increasing in strength and diminishing in rate. As a rule simple weakness does not contra-indicate general anesthesia. It is rather in the stout, flabby patient, past middle life, that one meets with the accidents of general anesthesia — accidents during its administration and postoperative. Even upon such unfavorable subjects profound anesthesia in itself so rarely produces evil effects that the dangers, definite though they may be, are unlikely to be lessened by methods whose dangers are as yet unknown.

In acute febrile diseases, especially typhoid fever, pneumonia, pleurisy, pyemia and septicemia, malignant endocarditis, purulent pericarditis, and the like, it seems a question whether the dangers of general anesthesia will be avoided by local or by spinal cocainization. The use of these doubtful methods in operations of emergency — as all operations in the course of acute diseases must be — seems ultraradical, if not, with our present knowledge, unjustifiable.

There is a class of cases in which these new methods find a reasonable application, and that includes the patients who from previous experience are known to behave badly under general anesthesia.

Another class inviting disaster under general anesthesia comprise operations upon deep cervical phlegmons, tumors close to and adherent to the trachea, inflammations and growths involving or pressing upon the recurrent laryngeal nerves. The largest number of emergencies that I have seen during general anesthesia have been of this class. It includes also imperative operations upon the trachea and larynx, such as tracheotomy for respirations obstructed by acute or chronic diseases, by foreign bodies, and by the pressure of tumors.

The value of local anesthesia in these cases is great. I recall 3 cases of impending suffocation during etherization for deep cervical abscess. It was impossible to free the throat, and inspiration was absolutely shut off. The first case occurred in the service of the late Dr. Hodges, and was saved by tracheotomy. Two were in my own service at the Massachusetts General Hospital and were saved in the same way. The necks were brawny and infiltrated, the jaws could not be opened, respiration became more and more labored, and finally completely prevented. Guided by this experience, which was many years ago, I have never approached a similar case without extreme caution when a general anesthetic was to be used. Cocaine has always been used when possible.

In the removal of thyroid tumors the selection of an anesthetic is very important. Three desperate emergencies in this operation have come under my observation, though none were my own. The first two required tracheotomy through the tumor. In the third, a patient of Dr. C. B. Porter, cocaine was at first used, but etherization became necessary before the operation could be completed. The larynx became totally obstructed, and life was saved only by tracheotomy after a rapid and brilliant dissection through the tumor. The tumor, which was supposed to be malignant, proved benign, and the patient has been well ever since. In all operations for tumors involving larynx or trachea, or pressing upon these structures, for lesions involving the recurrent nerves, the greatest emergencies may very unexpectedly arise.

We are apt to forget, in making comparisons, that the dangers of general anesthesia have been demonstrated in almost countless cases. A danger which is regarded by many of us too great to justify the use of chloroform does not comprise, even in the most unfavorable statistics, more than 1 death in 500 cases; in ether, a much smaller ratio. Who can believe that spinal cocainization will present as small an immediate danger as the general anesthesia of chloroform, a danger which is to me, for instance, so great as to be prohibitory. Were I to feel that one patient a year would die under the anesthetic alone, perhaps from a trivial operation or from one of convenience rather than of necessity — for a lacerated cervix, for example, or for lipoma of the back, or even for a thorough examination — the burdens and responsibilities of surgery would be beyond endurance. No operation requiring general anesthesia would be approached with equanimity; every moment of the anesthesia would be one of torturing anxiety. When ether is carefully given there is no distressing anxiety as to the outcome; I feel that the patient is as safe as he can be. A feeling of confidence is shaken only when the anesthetic is in the hands of the careless and overconfident, or the patient is in such desperate conditions as I have described.

I cannot believe that either spinal or local cocainization, after fifty years of use as extensive and varied as that of ether, or even of chloroform, has been, will show a safety to be compared with them.

EXPERIENCE IN SEARCH OF A CURE FOR ASTHMA IN THE FAR SOUTHWEST; WITH OBSERVATIONS OF THE COMPARATIVE VALUE OF DIFFERENT SECTIONS IN RESPIRATORY DISEASES.[1]

BY ROBERT BELL, M.D., BOSTON.

BRONCHIAL asthma is a disease with which we are very familiar, as every practitioner has had to wrestle with it in its victims. I will, for the better bringing the subject before us, briefly describe the conditions found in the disease and in a typical paroxysm.

By far the greater number of authorities classify bronchial asthma as a neurosis. In almost every case three conditions are constant: (1) A diseased condition of the respiratory tract; (2) an external irritant, as odors, dust, pollen or some subtle atmospheric condition; (3) a chronic neurotic condition. The most important of these is the third, for often after correcting or removing the first and second, the third remains to prevent the cure of the disease.

The typical spasmodic attacks of the disease usually follow an attack of ordinary bronchitis, though this is not always the case, as an attack may be caused, by the inhalation of some irritant, or by some gastro-intestinal disturbances. If there is but one attack in the twenty-four hours, it is usually between 12 and 4 A.M. Trousseau, who was a sufferer from the disease, said that he heard the clock strike three in the morning for many years. When the paroxysm comes on, the patient is waked out of a sleep suddenly, urgently pressed for breath. He sits up, throws the body forward, struggles for breath or coughs spasmodically for the purpose of clearing the respiratory tract of mucous. At first the tract is congested and dry, and expectoration is difficult. After continued efforts expectoration becomes more copious and breathing more free. In some cases of bronchial asthma cough is not a prominent symptom, though these cases are rare. Accompanying the cough, yellowish or grayish translucent masses are frequently expectorated. The writer has often untwisted these masses and found a spiral thread an inch or two in length. These spirals were investigated by Curschmann and found to consist of spiral filaments and swollen fatty degenerated pus cells and cells from the broncheoles. There are also found crystals called the crystals of Charcot and Leyden. These crystals are not pathogonomic, for they are found in other diseases. The sputum often contains crystals of calcic oxalate and of calcium phosphate. In my own case when the paroxysms are severe, the sputum becomes exceedingly salt to the taste, like sea-water, and is very irritating to the nose and throat. The sputum is usually white, thick and viscid.

As to the means of relieving an attack of asthma you are all familiar. Most speedily and effectively by the hypodermic injection of $\frac{1}{4}$ grain of morphine sulphate, with $\frac{1}{100}$ grain of atropine sulphate. This remedy easily becomes dangerous if continued. The writer has found the $\frac{1}{2}$ to the $\frac{1}{4}$ grain of heroin hydrochlorate as effective and more so; and there is little or no disturbance after it, as it does not interfere with the secretions and is not depressing. Inhalation of the smoke of belladonna, stramonium and lobelia leaves and of the powder of potassium nitrate give speedy relief though not always lasting. Grindelia robusta, quebracho, euphorbia pilulifera, asafetida and nitroglycerine are used internally, but are all of doubtful utility. Between the paroxysms potassium iodide and arsenic may be used. In a few cases they act wonderfully, but in most cases are of no value.

Change of location, or of climate has been found the best means of combating the disease, yet even this means often fails. Those who know most of asthma know that every case is a law to itself and that it is a most capricious disease, and that even slight and unpromising changes may work a miracle.

Before trying the West the writer tried nearer resorts, as Western Massachusetts, New Hampshire, Nantucket and Bermuda. Though in some of these places benefit was received for a short time, there was no permanent good obtained. The writer next turned to the arid regions of the far Southwest.

Places of high altitude, of dry atmosphere and of abundant sunshine do the most to relieve asthma. We find in Colorado the above conditions. Denver or Colorado Springs may be taken as types of what may be found in Colorado; the writer spent seventeen months in these places. The average temperature for January is 27° F, for July 73°, and for the year 50°. The annual rainfall is 14.4 inches. The relative humidity 50%. We have in Boston an annual rainfall of 46 inches, with a mean annual temperature of 49° F. The temperature of Colorado you will see corresponds very nearly to that of Boston, yet the dryness, rarified air, and large percentage of sunshine make the climate essentially different.

While in Colorado, I tried to get some statistics, from resident physicians, as to the value of the climate for asthma. The information I obtained from Dr. Josiah N. Hall, member of the Colorado State Board of Health, will cover all that may be known. He says that 50% of those under forty years of age without emphysema or other complication get practically well. You will see that this limits the cures to a very small number, as few escape emphysema, who have had the disease for even a short time. Of those over forty years of age without any serious complication, or those under forty years, yet with some complication, $\frac{1}{2}$ to $\frac{3}{5}$ get some improvement.

The writer next spent seven months in South-

[1] Read before the Norfolk District Medical Society, February 26, 1901.

ern California. Most of the time was spent in Pasadena and at San Antonio Heights, the so-called asthmatic belt. Though a few of the lighter cases of asthma are relieved in Southern California, it cannot be recommended for it, as there are many places so much better. Southern California is not a dry climate as is generally supposed. Though the annual rainfall is only 15 inches, there are frequent dense fogs, which bring the relative humidity up to that of many places east of the Mississippi. These fogs are everywhere except in the mountains. I regret to say this of Southern California as it is one of the most delightful sections of our country. There is so much of interest to see, its fruits and flowers are abundant and varied; society is the best and one can enjoy all the facilities and improvements of modern civilized life. With reluctance I turned away from Southern California as it aggravated rather than relieved my trouble.

The writer next tried Arizona, spending seven months at Phœnix, the capital of the territory. The elevation of Phœnix is moderate, 1,100 feet; the atmosphere is exceedingly dry; the winters warm. The temperature in December and January, the coldest months, only touching the freezing point and that for an hour or two in the early morning for a few days. In these months the temperature rises at midday to about 60° F in the shade, so that with the added heat of the sun it is possible to sit out-of-doors nearly every day. There is less wind in Arizona than in any other part of the United States. This is due to the fact that it is walled around by mountains of about 10,000 feet on every side except the east, which side needs no protection. The absence of high winds in these arid regions is a great desideratum, as the fine alkaline dust is abundant and is very irritating and annoying if blown about. The annual rainfall is from 8 to 10 inches. The annual temperature 72° F. The relative humidity 36%, and during many days may not be more than 5% or 6%. The summers are very hot, yet on account of their dryness are not so hard to bear as the months of July and August in Boston. These data refer to the moderately elevated parts of the Territory. If the heat is found to be oppressive it is easy to go to Prescott about 100 miles from Phœnix, where we can find a climate like that of Colorado and an elevation of 5,300 feet. Asthma is much benefited in Arizona and a large per cent. of cures are made.

If your patience will bear with me, and at the risk of some repetition, I wish to make a few observations on the comparative value of these different regions for respiratory affections. I will speak first of chronic nasal and post-nasal catarrh and dismiss them with a few words. These diseases are as prevalent and aggravated in Colorado and Southern California as they are in the East. This is due to some subtle atmospheric condition. Nasal and post-nasal diseases are much benefited in New Mexico and Middle Arizona. Chronic bronchitis is generally benefited throughout all the arid belt. The most important of all respiratory diseases is pulmonary tuberculosis, and of all treatment, climatic stands first in combating it. As we have a germ disease we must have conditions in a climate antagonistic to the growth of germ life, and conditions that fortify the resistance of the individual against auto-infection and against infection from the outside. The far Southwest meets these wants better than any part of our country. To antagonize germ life we need: (1) The greatest number of hours of sunshine possible; (2) dryness of atmosphere; (3) sun heat sufficient to promote sterilization, or constant cold to prevent germ growth; (4) a porous soil; (5) Freedom from dust and high winds. Colorado has all these conditions except the last. It also has a habitable elevation of from 5,000 to 10,000 feet, which is especially beneficial in early cases. It is possible to be out of doors most of the time, though the winters are often uncomfortably cold, and the winds in the spring especially high and dust storms frequent. The changes of temperature are often sudden and extreme. The cold of winter, the high winds and dust and the sudden changes of temperature are depressing to advanced cases of phthisis. Very nervous patients should avoid the high altitudes. Patients during the first months of their sojourn should rest a great deal. This is a hard thing to do, as the atmosphere is very exhilirating and stimulates to activity.

Dr. Carroll E. Edson, of Denver, very rightly insists on the value of rest, especially where there is fever and cough. Highly nervous patients often injure themselves by constant activity.

Southern California is frequently resorted to by the phthisical. Dr. Tyson, in the second edition of his valuable work on "The Practice of Medicine," writes, that Southern California has a dry, equable climate. This is a misconception, which is very general in the East. Considering the amount of rainfall, 15 inches, it would seem to be very dry, yet the dense fogs to which I have previously alluded, prevail over all Southern California, and can nowhere be escaped, except at an elevation above 2,000 feet. I would not condemn Southern California as a resort for the phthisical, as many of the earlier cases are benefited, yet I would not recommend it as there are many places so much better.

Arizona, in my judgment, stands first as a climate of value for all respiratory diseases. The physical reasons for this belief I have already noted in discussing the subject of asthma. From November, 1899, to May, 1900, during part of the writer's sojourn in Arizona, there were but three rain showers and these occurred at night.

If I were asked what place above all others I would choose for a patient with a chronic respiratory disease, I should say, Tucson, Arizona. It stands on a mesa of about 2,400 feet elevation. There is very little irrigation carried on near it. Its annual rainfall is from 8 to 10 inches. The mean average annual humidity 36 %. It is singularly free from wind, dust and sudden changes of temperature because it is nearly surrounded by high mountains. It has a maximum of sunshine and is

a desirable place to live in, meeting all the requirements of civilized life.

New Mexico has several desirable places suitable for health resorts. These places correspond very nearly to those of Colorado.

A few practical points for physicians to bear in mind, in sending patients to the far southwest. Be careful to send them in the first stage of their disease. Second and third stage patients may have life prolonged, but rarely recover. They should spend the early months of their sojourn in resting and living as much as possible in the open air. If a patient is highly nervous select a place of moderate altitude. If a patient is liable to hemorrhage, also be careful of high altitudes. Do not send from home a patient who is too weak to endure the fatigue of the journey. Do not send those who will be a tax on the charity of the good people of the West. Western people are very benevolent, and are willing to help and sympathize with the unfortunate, but the East ought to contribute much financially to the support of the sick and needy, for there are many who are stranded there, without money and without friends, and who suffer many hardships which they might have avoided by staying at home. Impress upon every patient that he is to remain in the West for many months, after his cough has ceased, and until he has regained and held his weight, and under no consideration should he return to the East, till he has received the sanction of a competent and experienced physician. It would be well if every patient sent, could from the outset be placed in the care of some good resident physician and there are many there of the best in our country, while by their side flourishes as a green bay tree every kind of fakir and "path" known, East, West, North or South.

CHOREA DURING PREGNANCY.[1]

BY F. S. NEWELL, M.D., BOSTON.

SYMPTOMATICALLY the chorea which occurs in pregnant women is identical with infantile chorea. The special conditions under which it develops, and the grave form it tends to assume in a large proportion of cases, give it a special significance, so that it deserves to be considered by itself as a definite complication of pregnancy, rather than as a modification of the more common chorea of adolescence.

Chorea in the adult, that is, in a patient who has never suffered from infantile chorea, develops usually during pregnancy — a period when the whole organism of the woman is subjected to marked alterations under the influence of the pregnant state. At this time, as at puberty, changes occur in the woman which involve all the important organic systems. The circulatory, digestive, and respiratory systems are all affected to a greater or less extent, and all the secretions are more or less modified; the nervous system is perhaps the most profoundly altered. At any rate it may be said that the effects of the pregnant state are most evident in the nervous system, and that all the other organs are more or less influenced by the condition of the nervous system.

Chorea deserves a special place in the pathology of pregnancy. It is not an accidental complication due to the recurrence of a previous infantile chorea, but in the majority of cases appears for the first time during pregnancy, that is, it is to a great extent, produced by pregnancy. Pregnancy is not the only causative factor, but is the fundamental condition on which the other elements in the causation of chorea depend. In 1851, M. See described the various elements which go to cause chorea in pregnancy as follows: "In pregnancy there exists a condition of chlorosis and hydremia, from which arise vascular disturbances, neuralgias, neuroses, and the loss of nervous equilibrium which accompanies them. These are followed by hysteria and chorea, separately or together; one predominating in accordance with the antecedent history of the patient. Add to this nervous instability a marked predisposition to rheumatism, and the effect of pregnancy as the immediate exciting cause becomes evident, acting in the presence of the same predisposing causes which exist in the chorea of children."

Etiology and pathology. — From the standpoint of etiology all the factors which have been considered as predisposing to infantile chorea are to a great extent active in the chorea of pregnancy. The nervous system of the patient presents an impressionability either hereditary, or acquired from some previous affection. There seems to be little doubt at present that a tendency to chorea may be inherited. Huntington has shown conclusively in his genealogical tables that chorea exists in certain families for generations, and that in a considerable proportion of cases, the first manifestations of the disease become apparent during pregnancy. Lannois, Charcot and others, agree on the importance of heredity as an etiological factor in many cases. This predisposition is not, however, evident in every woman whose forbears have had chorea, as numerous examples prove that chorea may skip a generation, or die out, in a given family.

Another important factor in the etiology of the chorea of pregnancy is the existence of a previous chorea during childhood. A woman who has once suffered from chorea, whether mild or severe, is liable to a return of the disease during her first pregnancy. Barnes says "Pregnancy furnishes a proof of the cure of chorea." It is far from being true, however, that every woman who has chorea during pregnancy has had a previous attack during childhood. Of 96 cases which Charpentier records, only 20, or about 27%, gave a history of a previous chorea. Pinard, on the other hand, reports that of 8 women in his practice who developed chorea during pregnancy, 7 had had a previous attack. Chorea is most apt to manifest itself for

[1] Read before the Obstetrical Society of Boston, December 18, 1900.

the first time during the first pregnancy, but the rôle played in the etiology by the first pregnancy must not be exaggerated, for of 107 cases reported by Barnes and Bamberg, only 56 were primiparæ. Young women are most apt to be affected, chorea seldom appearing for the first time after the age of thirty. When a woman has had chorea in one pregnancy it is apt to recur in subsequent pregnancies in a more and more serious form, although the reverse of this may occur. For the evidence on this point to be of marked value it would be important that the same observer should follow the patient in all her pregnancies, and in hospital practice, from which the bulk of the cases are reported, this is unusual.

It is a difficult matter to determine the influence of rheumatic fever, chlorosis, hysteria, and the infectious diseases and auto-intoxications in causing an attack of chorea. The etiological importance attached to these various elements varies according to the prevailing belief at the time at which the cases were reported and the weight of authority carried by the various observers. For a long time, from the observations of Roger, See, Jules Simon, and others, chorea among children has been believed to be closely connected with rheumatism. This applies only to a slight extent to the chorea of pregnancy, for the majority of patients who develop this disease give no history of a previous rheumatism. Charcot admits a certain doubt of the etiological importance of rheumatism when he says: "In my opinion there is not a rheumatic chorea in the strict interpretation of the phrase. In other words I do not believe that chorea can even be considered as the equivalent in the nervous system of the articular or visceral changes of rheumatism. It seems to me, however, that although the opinion I am opposing is the result of error, there is no doubt that chorea and articular rheumatism often exist together either in the same individual or the same family. The common coincidence or alternation of the two diseases is not enough, however, to show that they are identical or even closely related. It simply shows the existence of a certain affinity between them, the cause of which is unknown."

From the standpoint of the nervous system the analogy between the changes which occur in the system at puberty and during pregnancy may be cited to support the view of Jeffrey in regard to the etiology of Sydenham's chorea. He considers it a disease of evolution, affecting the cerebro-spinal system and allied closely to its development. The general opinion of authorities today, especially in England, is that the chorea of pregnancy is entirely of nervous origin. They consider it to be a neurosis, due to the stimulation of the utero-ovarian plexus. Barnes laid stress on the relation of the establishment of the menstrual function and the development of chorea, and Barton-Hurst reports a curious case of chorea in which the movements were increased at the time of the periods. Fontenau explains the physiology of the disease in this way. "In pregnant women the excitation of the nervous system begins in the utero-ovarian plexus, and passes through the great sympathetic to the cord and brain, and thence to the muscles through the motor and sensory nerves. In these cases there arises a depression of the intellectual centres, which should inhibit the movements, due either to hyperstimulation, or, on the contrary, to a complex mechanism analagous to that described by Brown-Sequard."

Whatever physiological explanation may be invoked to give the key to the choreic movements, the fact remains that the whole organism is in a state of unstable equilibrium ready for the stimulus which causes the outbreak. This state of nervous instability is closely related to hysteria, and has caused at times more or less confusion between hysteria and chorea. The hysterical stigmata are, as a matter of fact, to be noted in a large proportion of the cases of chorea during pregnancy. If it is admitted, as has been claimed, that chorea is a manifestation of hysteria in pregnant women, it is possible to assert that infantile chorea is only infantile hysteria. Whether we place the cases of chorea with hysterical stigmata in a group by themselves, or class the cases under the head of hysteria with choreic movements, the fact remains that hysteria is a predisposing cause of chorea during pregnancy.

Previous infectious diseases probably have an etiological importance in chorea, in that they prepare the ground for its development. This theory has been thoroughly discussed by Triboulet. Although he eliminated from his study of chorea the cases occurring during pregnancy, his conclusions apply to them equally as to the infantile cases, and in investigating the previous history of the patients it is often possible to get a history of a previous infection which will give the clue to the etiology of the chorea. Furthermore, auto-intoxication is so frequent in pregnancy that it is unnecessary to invoke the aid of external infections to establish a satisfactory etiology for the chorea. Duchateau, in his classification of chorea, places the chorea of pregnancy under the heading of "chorea of auto-intoxication." When we remember the disturbances which arise in the functions of excretion and assimilation during pregnancy, and the rôle they play in eclampsia, there is some reason for considering chorea at this time as more or less closely analogous to eclampsia in its origin.

Pregnancy, alone, is no more to be considered as the direct cause of chorea than is active growth in children the cause of infantile chorea. In almost all well-marked cases of primary chorea during pregnancy, some more or less violent nervous shock is the apparent starting point of the trouble. Jaccoud reports a patient who was seized with violent choreic movements after a violent family quarrel. Mosler's case developed after a slight fall. Bamberg's case fell into the water. Hand's case fell from a ladder. Kemper's case waked at night to find the house on fire and was seized next day with violent choreic movements. Certainly, if it is true as has been said, that mental shocks "are the cause, whose active influence

can be pointed out in all the neuroses," it is impossible to deny their influence in the causation of chorea in pregnancy.

Symptoms. — The disease occurs most commonly in young women from eighteen to twenty-four years old. It is relatively common from twenty-four to thirty, but very rare after that age. It usually occurs in the first pregnancy but occasionally it occurs for the first time in later pregnancies. It may begin at any period of the pregnancy. In some cases its beginning coincides with conception, and it has been said to be one of the earliest signs of pregnancy. It most commonly develops during the first five months, although it occasionally does begin in the last four months of pregnancy, becoming the more rare the nearer to term. A few cases have been reported in which the choreic movements have first made their appearance after delivery.

In the majority of cases the movements come on gradually, becoming more violent as the time of delivery approaches. In certain cases, however, the onset is violent and the progress rapid, acquiring a considerable degree of intensity in a very short time. In other cases periods of remission and exacerbation alternate. The movements are usually bilateral, although at times only one side is involved. Hemichorea is very rare, however, although one side is usually affected before the other. The intensity of the movements is apt to be much greater on one side than on the other, being more marked on the side which was first involved.

Prodromal symptoms may or may not be present, but when present are apparently nervous in their nature. The temperament of the patient may change abruptly, and marked irritability and loss of self-control develop. Loss of memory and hallucinations of sight and hearing may be present. If these symptoms do not precede the outbreak of chorea, they often accompany it and form part of the general picture of the disease. The choreic movements most often begin in the left hand and arm. The hand flexes and extends on the forearm. The simultaneous or separate contraction of various groups of muscles in the arm produces movements of pronation, supination, or flexion of the forearm, in accordance with the muscles involved. The movements are involuntary and abrupt, and become exaggerated if the patient tries to control them. The fingers become useless for the more delicate work the patient is accustomed to use them for, and the attempt at grasping objects in the most ordinary acts of life shows an awkwardness which is diagnostic when noted. In a short time the other arm and the lower limbs become affected. This results in an alteration in the gait, and in the sitting posture, and in a series of abrupt changes of position as strange as they are unexpected. When the patient tries to remain motionless in the standing position, an abrupt contraction of the extensors changes her centre of gravity, and necessitates a series of awkward movements in the attempts to regain her balance. In severe cases walking is rendered difficult or impossible by the inco-ordination of the muscles.

The abrupt abnormal contractions may be observed even in the body and shoulders. The respiratory muscles may be affected in severe cases to such an extent that breathing, particularly slow and sustained expiration, is rendered difficult. All the muscles of the head and neck may be involved so that not only the muscles of facial expression, but also those of the pharynx and larynx may be the seat of twitchings. The movements cease during sleep, but only when ideation is completely suspended, for example, in sleep without dreams. According to Jaccoud, the mental process which produces dreams stimulates the medullary axis, as in the waking condition, and produces inco-ordinate movements, less marked it is true than when the patient is awake, but still unmistakable.

The mental disturbances which accompany Sydenham's chorea are found in certain cases of the chorea of pregnancy before the motor disturbances. Modifications of the moral sense, imperfect ideation, and hallucinations may be present. Sleep is apt to be restless and troubled by dreams. Mania and dementia have been observed.

The nutrition of the patient suffers in grave cases from the difficulty of feeding the patients, and from the great exhaustion which accompanies the incessant muscular activity. The spasms of the soft palate and lips favor the introduction of food into the air passages.

The fetus may, in mild cases, live and be born at term. In severe cases it usually dies and causes abortion or premature labor.

The chorea usually lasts during the whole term of gestation and sometimes days or weeks after delivery. As a general rule the spasms become less violent after delivery, a fact which indicates the appropriate treatment in severe cases. This is not an absolute rule, however, and in any case after a temporary amelioration the spasms may again increase and become chronic. Hart reports 3 cases in which the chorea, after repeated attacks in successive pregnancies, became chronic. Cardiac complications may appear as in infantile chorea, but in a much smaller proportion of cases. They are more apt to occur in the severe cases than in the milder ones. In grave cases a rapid loss of strength occurs, and such a degree of emaciation and debility may be produced as to render the loss of blood which accompanies abortion or premature labor, a serious if not a fatal complication. A fatal termination may occur before the expulsion of the fetus in patients in regard to whom a temporizing method of treatment is adopted. Although it is to be considered in all cases a serious disease, with a doubtful prognosis for the future, it is in many cases definitely cured, or may only leave slight traces.

Prognosis. — The disease is a rare one during pregnancy, and months may go by in a large hospital without a single case being seen. Considering, however, the short time that a woman is under observation in a lying-in hospital, it is probably true that many cases in which the movements are

very slight are not included in the published statistics. It is also true that the choreic movements may not attract the attention of the obstetrician sufficiently to be reported, unless they threaten the continuance of pregnancy. These facts explain the difficulty of obtaining the true statistics of chorea, especially the percentage of its occurrence. For this reason any prognosis based on statistics is unreliable.

The mortality in the published tables varies from 1 in every 17 cases to 1 in 3½ cases. In the more recent papers the statistics are better and more cases are reported. Pinard says the prognosis which would have to be given, if the published statistics were relied on, is more grave than the true condition of affairs warrants, provided that the patients receive adequate treatment. Nevertheless, the prognosis of chorea in pregnancy is much more grave than in early life. The fetal life is always seriously compromised. According to the older statistics, pregnancy is interrupted in one-half the cases. According to later reports the prognosis for the child is better as well as that for the mother. Pinard reports, in 8 cases, 8 well-nourished infants at term. The viability of the infant necessarily depends on the general condition of the mother as well as on the severity of the chorea and its complications. Children born from choreic mothers occasionally show choreic movements soon after birth.

Treatment. — In the treatment of chorea the principal drugs which are used are the sedatives, bromide, chloral and morphia and the alteratives, arsenic and iron. In grave cases ether and chloroform may be given as in eclampsia. Rest in bed and freedom from worry are also valuable adjuncts to treatment. Every effort to improve the general nutrition of the patient should be made. Pinard uses large doses of chloral to the point where the patient is in a condition of continuous sleep. She is only waked for food. This treatment is continued until considerable improvement in the choreic movements occurs. The doses are then diminished, but are continued until the movements entirely disappear. In very grave cases the early induction of abortion or premature labor is imperative. The success of the sedative treatment serves to demonstrate the importance of the nervous element in the chorea of pregnancy, which differs from ordinary chorea more in its nature than in its symptomatology.

M. F., age nineteen.

Previous history. — Measles, scarlet fever; no other children's diseases. When twelve years old had chorea for the first time. For the next five years had an attack every summer. No sign of chorea during the cold weather. Last attack two years ago. Much more severe than previous attacks. Could hardly speak, and could not use hands to any extent. Catamenia regular, except during the previous attacks of chorea, when at one time she skipped five months. Last catamenia began May 6, 1899; normal in every way.

Present illness. — In June first noticed that speech was abnormal. Enunciation difficult. In July hands began to twitch. Left side was first affected, then right side. Lower limbs slightly affected in August, but not enough to interfere with locomotion. At this time she first came under observation.

Physical examination. — Slight, anæmic girl. Mucous membranes very pale. Heart not enlarged. Slight systolic murmur over apex, not transmitted to axilla. Marked twitching of face and hands, especially on left side. Lower limbs slightly affected. Speech was very thick, and enunciation was difficult. Twitchings of hands so marked that co-ordinate movements were impossible.

Treatment. — Fowler's solution in increasing doses until the physiological limit was reached; then given in five-drop doses three times daily. Rest in bed and careful feeding formed the rest of the treatment.

Contrary to the usual rule in these cases, the symptoms yielded promptly to treatment and absolutely disappeared during the eighth month, so that at the time of her confinement in the Lying-In Hospital there was absolutely no evidence of the affection.

In many ways this patient afforded a typical example of the chorea of pregnancy. The affection developed before the diagnosis of pregnancy could be made, and if the full history had been known at that time would have furnished a valuable sign in the diagnosis of the pregnancy. The marked chlorotic condition was apparently the exciting cause of the disease. The choreic movements began on the left side, but later became bilateral. The circumstances of the patient were such that no efficient treatment could be carried out where she was; but after her admission to an institution where quiet and proper food could be obtained, her progress was more rapid and the unexpected result of entire cure before delivery was obtained. This would suggest that in this case the pregnancy was not responsible for the chorea except in so far as it acted to produce the abnormal conditions of the blood and nervous mechanism on which the development of the chorea depended, since, when these conditions were relieved to a certain extent, the chorea disappeared in spite of the existence of pregnancy.

To give some idea of the frequency with which chorea complicates pregnancy, a study of the records of the Lying-In Hospital shows that in about 11,000 cases there have been 13 cases of chorea. Eleven of these cases were primiparæ, and gave a history of previous attacks during childhood. One of the others was a multipara in her third pregnancy, and gave no history of previous attacks either in childhood or with her other children. The last case was a secundipara; chorea in childhood but not in first pregnancy. In ten of the patients the movements entirely disappeared within a week of delivery, and in the other 3 the movements were very slight at discharge. None of the cases were severe enough to require active treatment, and in all of them, except for a slight irregularity of temperature during the convalescence, the progress was normal.

NOTES ON X-LIGHT.

BY WILLIAM ROLLINS, BOSTON.

THE ECONOMICS OF THE X-LIGHT TUBE.

A PROPERLY prepared x-light tube deteriorates in use. No practical means for preventing this are known, though vacuum regulators which introduce fresh gas into the tube are supposed to accomplish the result. The deterioration of a new tube shows itself by the light becoming of such character that it will not penetrate the tissues. If this difficulty is overcome there is a short period during which the tube is valuable, though with a powerful apparatus it lasts but a few hours; the resistance of the tube steadily rising, until the light penetrates the bones almost as well as the flesh; the tube becoming useless, because it does not properly differentiate tissues differing little in density. At last no current will go through. With a powerful apparatus, especially a high frequency generator, the whole process is one of a few hours only.

What is the cause of the phenomena and what the remedies? As any theory which will serve as a working hypothesis is better than none, I give the one used in my attempts to make an efficient x-light apparatus.

To produce x-light we depend upon gases amalgamated with the metal terminals in a vacuum tube. These particles are driven by the electric current, from the cathode against the target where they are heated to such a high degree as to become radiant centres from which x-light arises. The higher the velocity of impact the greater the temperature and the more penetrating the light. On this theory the process of "pumping" a tube does not consist in simply removing the air but is twofold. Enough air must be taken out to allow the gas particles shot from the metal of the cathode by the electric current, to have a comparatively free path on their way to the target. So much gas must be driven, by electricity, from the metal of the terminals, that the electric stress will not make it come out too fast when the tube is used. The effect of producing x-light according to this theory is to necessarily bring out these gases. If they did not come out and we depended upon the air in circulation in a tube we should not have an efficient cathode stream and sharp

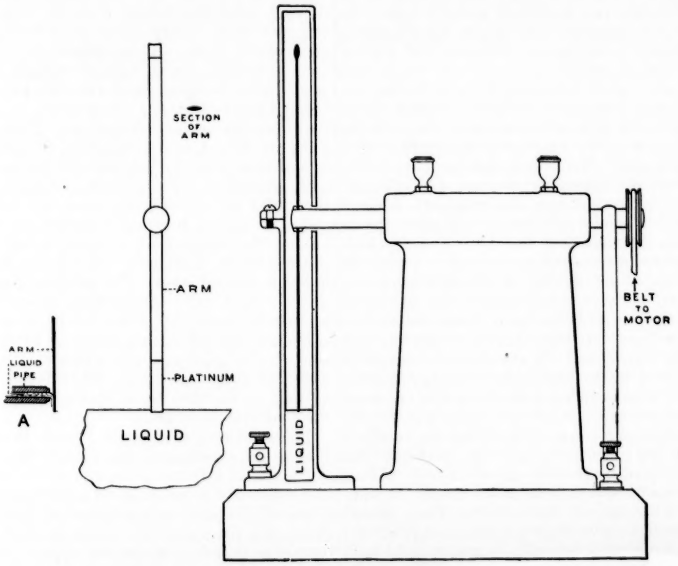

FIG. 8.

definition. The effect of use, then, is to lower the vacuum in an x-light tube. As a result the particles forming the cathode stream must meet with more obstruction from the increased density of the mist filling the tube, through which they must force their way to the target, consequently they strike with less velocity, are heated to a less degree, and give rise to a kind of light which is unsuitable. By means of a reservoir and movable dam, outside the tube, the current may be held back and sent in powerful surges which impart a higher initial velocity to the cathode stream particles causing them to strike the target at a sufficient velocity, in spite of the increase of the mist through which they must force their way.

After a time the continued formation of a cath-

ode stream so reduces the number of particles in the metal, that the current finds more difficulty in passing; charging each particle therefore to a higher degree, producing in it a higher velocity and causing it to strike the target so hard the resulting light becomes of more and more penetrating character. This is the explanation of the second stage, the advancement to the third state being hastened by the fact that the cathode stream particles are absorbed to a certain extent by the glass walls of the tube. The third state is but a continuation. The particles have still further diminished in number — those remaining are more tightly held by the metal — the current cannot separate them unless the potential is increased: the tube gives no light, for no current is sent by means of the cathode stream. What is the remedy? The one in universal use is to introduce gas into the tube. Crookes recommended water vapor. In earlier notes formulæ were given for chemicals which liberated oxygen or nitrogen, but finding that the cathode stream spectrum was chiefly that of hydrogen I gave directions for introducing this gas expecting it would be the ideal regulator, but more powerful generators showed that simply introducing it would not restore the pristine brilliancy of a tube. No common gas put into a tube will permit it to continue to give a satisfactory light with the expenditure of a reasonable amount of power. The effect of introduciug more gas is to increase the density of the mist through which the cathode stream must force its way. When the particles move too rapidly, as in a high resistance tube, where no gas has been introduced, the introduction of gas retards them and alters the character of the light, but the effect is temporary and the theory a poor one. If my theory of x-light is true, we need to do something entirely different, namely, to restore the same kind of gas to the metal of the cathode as has been used up in making the cathode stream. I have given various methods for doing this imperfectly, but the chief problem in x-light tubes is to find the ideal way. Until the problem is solved generators should be constructed to conserve the supply. They should also be made to give high potentials, that an external reservoir and dam may be used to hold back the current and send it in powerful surges when, as in a new tube, the mist is increased by the cathode stream, or in an old tube by introducing more gas than was intended. The importance of this is well shown in Fig. 87, *Electrical Review* for Dec. 26, 1900. The negative had an exposure of twenty-eight minutes without such a reservoir and dam, the plate not being acted on; while in Fig. 88, the use of a reservoir and dam produced a good picture with the same tube in twenty-eight seconds.

To economize the supply of gas in the metal the surges should be of the shortest possible duration and yet of sufficient volume to produce the required light. The tube should then rest, until to make the light continuous to the eye, another surge must be sent. Twelve hundred surges a minute are enough. The volume of each should be several horse power if we wish to advance rapidly in the differentiation of tissues in the thick parts of the body with the fluoroscope. When I attempted to work in this direction with static machines, even the most powerful one made, which I constructed for my experiments, had neither potential nor amperage enough, though the plates averaged two metres in diameter and weighed over a ton. For the present, then, coils are better, but the insulation should be more perfect, for those in use are quickly spoiled by less powerful surges than it is desirable to use. I have found that micanite is the only material suitable for insulation between the primary and the secondary. I am indebted to the Micanite Company for their co-operation, for without it, experiments with heavy surges would have been abandoned, until Trowbridge placed his generator within reach. As the duration of a surge may depend upon the break, it is of importance to improve this. Only some modification of the electrolytic break of Spottiswoode (1876) will bear powerful surges without rapidly deteriorating. I have designed breaks on this principle, one being shown (Fig. 8). It consists of a covered tank containing an electrolyte. Two platinum arms are caused to revolve in such position that one of them may dip into the solution once during each revolution. The second arm does not touch the liquid, its object being to act as a balance. If the shaft makes fourteen hundred revolutions a minute the duration of a surge is but a twenty thousandth of a minute. It may be further reduced in several ways. The solution may be lifted into a tank and discharged from an orifice against the arm. Or a second break may be introduced into the circuit, the time of the immersion of the platinum not exactly corresponding with that of the first break. The effect is to deliver current to the first break during only a part of the time it is immersed.

Before closing this paper I wish to call attention to an experiment by Trowbridge in 1898. By means of a Plante generator of his own design and construction he obtained a photograph of the bones of the hand in a millionth of a second. In doing this he placed the mark so high that few have seen it and no arrow has approached it. The experiment was of the deepest significance encouraging me to go on experimenting with higher potentials for producing x-light.

Conclusion.—The most important discovery to be made in x-light tubes is to find how to keep the character of the light constant. Meanwhile the best way to excite an x-light tube is to use surges of millions of volts and many horse power, each surge lasting for not more than a millionth of a second.

AN X-LIGHT PLATE HOLDER.

There are two methods in use for protecting sensitive plates in making photographs by x-light. The plates are wrapped in colored paper, or the ordinary wooden photographic plate holders are used. Both methods are undesirable, for an x-light tube fills a room with a bright though invisi-

ble light, which, dashing about in every direction, fogs the plate or even makes images on it of objects on the opposite side from the body being photographed[1]. No x-light should reach a plate except what comes through the patient being

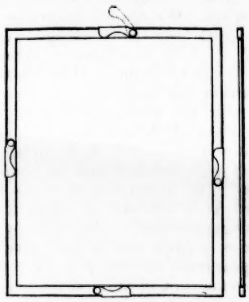

FIG. 5. — X-LIGHT PLATE HOLDER.

photographed. A first requisite in an x-light plate holder is a means to achieve this; (2) the plate holder should bear the weight of a patient without risk to the plate, even though it is necessary for him to sit on it; (3) it should be thin

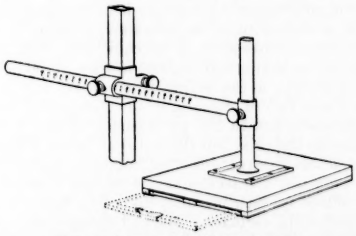

FIG. 6. — SUPPORT FOR PLATE HOLDER.

to avoid discomfort to the patient when he lies on it; (4) it should be moisture proof to protect the plate from perspiration. I have used for several years metal plate holders which meet these and other requirements. The latest and simplest

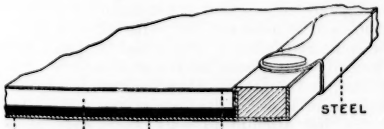

FIG. 7. — SECTION OF PLATE HOLDER.

plate holder is shown in the figures. Total thickness seven millimetres. It is in two pieces, a back of nonradiable, a front of radiable metal (aluminum) held together by steel clamps. A support for the holder was shown in Fig. 2 illustrating an x-light table in a former note.[2] Another support attached to the upright shown in Fig. 2 is illustrated in Fig. 6.

[1] Electrical Review, April 11, 1900, note 94.

REMOVING THE IRRITATING GASES PRODUCED BY X-LIGHT GENERATORS.

A powerful x-light generator produces ozone and combinations of nitrogen and oxygen. These are irritating to the respiratory mucous membranes. A fan should be placed within the case of a static machine to drive the gases into the nearest chimney. A coil should have the spark gaps enclosed as shown in Note 112[3], the gases being drawn by an aspirator into the waste water pipes.

Clinical Department.

A SPECIAL FORM OF PHLEGMON OF THE NECK.

BY F. P. EMERSON, M.D., BOSTON.

IN 1893, under the above title, in the *British Medical Journal*, Drs. Brousses and Brault published an article describing a suppurative process enclosed in a space of prismatic form, situated below the back part of the tongue, and bounded in front by the hyoglossal and thyrohyoid membranes and behind by the anterior surface of the lower and attached portion of the epiglottis. The upper boundary is formed by two membraneous layers, one consisting of the lingual mucous membrane; the other and deeper layer of fibrous tissue. This cavity it is stated is divided into two lateral halves by a membraneous septum, which seems to be an extension downwards of the median glosso-epiglottidian ligament. This enclosed and divided space, which is called by the authors the glosso-thyro-epiglottidian cavity, may, it is stated, become inflamed and thus give rise to diffused phlegmon of the neck.

Mrs. S., Roxbury, age sixty-four years, born in Bangor, Me. Father died age seventy-six, carcinoma of stomach; mother died in childbirth; five brothers died young; one sister died of carcinoma, and one now has it. Has had three children. Measles at ten years. Formerly subject to tonsillitis, but for the last ten years exempt and her general condition good. Last three months nervous and debilitated. Had been having sinking spells which she referred to her heart. During the last week has been having a naso-pharyngitis and tonsillitis. Dr. H. was called in December 29th and found her pulse irregular but not increased in frequency. Temperature 99°, and some dyspnea. On December 30th he was called at 6 A.M. Patient aphonic but no urgent dyspnea; at 9 A.M. dypsnea somewhat more pronounced, and by noon attended by cyanosis, anxious facies and great difficulty in deglutition. At this time I saw her in consultation and found the following condition.

Examination. — Externally inspection shows the neck uniformly swollen down to the clavicle, presenting a three-lobed tumor separated by membraneous septæ, full and resistant throughout. No cervical glands; no redness; sensitive to pressure and of a woody feel. Great difficulty in swallowing and breathing. Pulse normal and fair quality. Subjective feeling of depression and weakness increased by loss of sleep during the preceding two nights. Facies anxious. Laryngoscopy shows a general laryngitis, with the lumen uniformly encroached upon. The alignment of the vocal chords normal but covered by the ventricular bands. No edema or paralysis; no exudate. Tonsils and pharynx not now abnormal. Culture shows no bacilli of diphtheria. Epsom's salts had been administered. The dyspnea was not sufficiently urgent to require immediate action, and as the case had gone along for a week it seemed probable that twenty-four hours might show a beneficial change.

Ice poultices, alternating with unguentum resorcin, one drachm to the ounce of lanolin, was recommended; also cracked ice and a steam spray of campho menthol, with supportive treatment, was given.

On December 31st pus was seen to be exuding from the left side of the larynx. The discharge was gradual. The deglutition improved and convalescence was uneventful.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

(Concluded from No. 16, p. 380.)

INJURY OF THE SPINAL CORD.

HARTMANN[7] has made an elaborate clinical and pathological study of 8 cases of injury of the spinal cord. He recognizes a true commotio spinalis, that is, a disturbance of the cord giving rise to well-marked spinal symptoms, which disappear entirely in a week or so. The more severe spinal conditions are divided into two classes: those complicated with lesions of the vertebral column, and those not associated with such lesions. This latter class is again subdivided into two classes: in the first the disease follows the injury immediately, and in the second a chronic spinal disease develops as a late result of the injury. In this last group he reckons chronic anterior poliomyelitis, sclerosis, gliosis, sclero-gliosis and syringomyelia of traumatic origin. In studying the mechanism of injuries of the cervical cord he distinguishes those due to direct injury, and those due to indirect injury. The latter arise from the peculiar structure of the vertebral column — a rigid thoracic portion and a movable cervical portion — and the forces exerted by the position of the head in falls upon the back (the natural tendency to flex the head and the force exerted by the weight of the head). In this way lesions of the cervical cord may arise indirectly from violence applied to the thoracic vertebræ. The histopathology of those uncomplicated, directly traumatic affections must be considered separately as to the various tissues, since our pathological conceptions of inflammation, etc., are still obscure. We cannot determine definitely the pathological basis (hemorrhage, necrosis, inflammation, etc.), of a traumatic spinal disease from the clinical symptoms. The diseases of the different tissues naturally vary in intensity, and this fact, with the pathological changes in the reciprocal action of these tissues, forms the basis for the difference in the anatomical changes. The primary degenerations may be lymphogenous or ischemic. The degeneration of the periphery of the cord is a mixture of these forms with secondary degenerations. The tendency to regeneration varies greatly and it may give the anatomical appearances the stamp of a lymphogenous primary degeneration of nerve substance or a more active regeneration of connective tissue resembling a non-purulent inflammation.

Among the pathological processes he distinguishes in the membranes, hemorrhage, cicatricial contraction and adhesive meningitis; in the lymph apparatus, lymph stasis, lymph infiltration, lymphogenous degeneration (Schmaus's primary necrosis), and cavity formation; in the vascular system, primary and secondary hemorrhage, hyperemia, proliferation of endothelium, changes in the adventitia, obliteration of the capillaries with consecutive ischemic degeneration, true periarteritis and arteritis; in the neuroglia, moderate proliferation about foci of disease, in the peripheral zones of the cord, and in the perivascular spaces with a change in the cells; in the nervous tissue, primary mechanical destruction, lymphogenous and ischemic necrosis, diseases of the roots and changes in the cells of varying intensity and often remote from the seat of the violence. Marked changes may arise primarily without any hemorrhage. The lesions in the cells and roots are not as dependent upon the seat of the injury as are the general changes in the cord, and we thus find disseminated foci of disease, degeneration of the roots and changes in the cells at a considerable distance from the point of greatest alteration, and these remote lesions may also influence the clinical symptoms.

Chipault[8] shows that arthropathies of a trophic nature are occasionally met with after injuries of the spine and spinal cord and also in spinal caries. Clinically they somewhat resemble tabetic arthropathies, and sometimes they are exactly similar to them, as in a case of fracture of the spine, where, at the first attempt to walk, there suddenly developed an enormous swelling of the right knee. Most of the arthropathies following injury or caries, however, develop under the form of an effusion with little or no deformity, since the patient is confined to his bed, and thus is less liable to injure the joint by attempting to walk; while tabetic patients increase the joint trouble by keeping about. The arthropathies in the cur-

[7] Jahr. f. Psych., xix, 380, 1900.

[8] Trav. de neur. chir., v., 76, January, 1900.

able forms of spinal injury often assume the form of a slight effusion, and they may be permanently cured instead of increasing to the severer forms seen in tabes.

HEMATOMYELIA.

Lépine[9] has collected 227 cases of hematomyelia and has supplemented his study of these cases by various experiments. The predisposing causes, — sex, age, and manner of life — are of slight significance. Injury is responsible for about 90% of the cases of primary hematomyelia and congestion for the rest. Injury is due to fracture or dislocation of the vertebræ, stretching of the cord (from forced movements of extension of the trunk, from suspension as in the treatment of tabes, and from certain obstetrical maneuvers), stretching of the spinal roots, and simple commotion of the cord. The cases which follow violent convulsions, exposure to cold and sexual and alcoholic excess are probably due to congestion.

Hematomyelia may also follow the rapid change from high to low atmospheric pressure in coming out of a caisson. Hematomyelia may also occur secondarily in acute or infectious myelitis, thrombosis or embolism of the cord, chronic myelitis, syringomyelia and tumors; but only 38 out of 227 cases were secondary. Lépine found that, by injecting blood into the cord after a previous laminectomy, he could reproduce the conditions of primary hemorrhage. The blood expands by preference upwards in the gray columns, but not into the anterior horns which seem to resist. The central canal is the chief channel for extending the hemorrhage, and the tissue about the hemorrhage becomes softened. Simple puncture provokes diffuse capillary hemorrhages, especially in the gray matter, with secondary myelitis of the gray matter and dilatation of the central canal. Commotion of the cord from shock gives rise to immediate and late lesions: the former consist of an intense congestion of the injured portion, with extravasation, myelitis, and a moderate reaction of the neuroglia, the intensity of which is related to the number of hemorrhages. The transition to normal pressure, as in coming out of a caisson, causes gaseous emboli and hemorrhagic infarctions. The latter are due to the rupture of the vessel walls from the enormous dilatation caused by the local development of gas and the afflux of blood from the acutely dilated intestines. The capillary hemorrhages are less important; the larger hemorrhages occur most frequently in the cervical region, rarely extending to other parts of the cord: they also occur chiefly in the gray matter about the central canal or in the posterior horns, occasionally involving the white substance, but leaving the anterior horns intact. Lépine gives no definite answer to the question whether such hemorrhages can originate a true gliosis and thus be transformed into a syringomyelia. His contention that the anterior horns are usually intact and resist the entrance of blood is, however, somewhat too positive. Minor, Fischer and various other writers have reported cases with autopsy where the hemorrhage involved the anterior horns, and other cases are on record where the symptoms warranted the diagnosis of a hemorrhage in this region.

[9] Etude sur les hématomyélies, Thèse de Lyon, 1900.

APRAXIA.

Liepmann[10] has made an exhaustive study of the very interesting case of a man who apparently presented the symptoms of sensori-motor aphasia with profound dementia, although in reality he had only motor aphasia with a fair amount of intelligence, and apraxia, or inability to use the limbs intelligently on the right side. The patient used the right hand exclusively to execute the movements suggested to him, and his acts did not correspond to the commands, so that they were often absurd and ridiculous; and when he used both hands, the left hand could not correct the mistakes of the right. It therefore seemed as if he did not understand what was said to him; but, when the right hand was held, he could execute orders correctly and even work a little with the left hand. The apraxia did not appear in all movements. Those performed by the body as a whole, sitting, rising, walking, etc., were normal; and certain complex movements, usually affected in apraxia, such as buttoning and unbuttoning the clothing, pointing at an object, eating with a spoon, etc., were also normal. The motor disturbance was, however, evident in all co-ordinate movements which demanded the association of coenesthetic representations with optic and acoustic representations, that is, in movements which required the directing action of the whole cortex. Certain other movements, such as indicating a part of the body, were also impaired. The apraxia was limited to the right side only in movements performed by the limbs; in the face it was bilateral, giving rise to paramimia. After very elaborate examinations and tests Liepmann determined that the trouble was not due to any error of identification, to any agnosis or asymbolia from psychical blindness or deafness, nor to any anesthesia, although there was a diminution of sensibility in the limbs on the right side and an inability to determine the position of the limbs with the eyes closed. He believes the apraxia was due to a loss of the representations of movement on the right side, that is, to a loss of the ensemble of coenesthetic, optic and acoustic representations which contribute to the production of a complex movement. It is therefore a motor asymbolia, as distinct from a sensory asymbolia. The motor centre in the cortex may be injured, therefore, so that it no longer receives impressions from the other cortical centres, and yet it may still respond to sensory stimuli coming from the periphery. The lesion, which was probably syphilitic, he believes, spares the central convolutions, but involves the supra-marginal gyrus and the superior parietal convolution, thus separating the central convolutions from the visual and auditory centres. It also must extend into the third frontal convolution and perhaps the

[10] Monats. f. Psych., viii, 15, 102, 182, July, August, September, 1900.

island of Reil, on account of the motor aphasia. The lesion would therefore lie in Flechsig's posterior association centre. The symptom, if the localization be correct, ought to be found much more frequently than at present, considering the comparative frequency of lesions in this region.

HYSTERIA.

Steffens[11] discusses the differential diagnosis of hysteria and epilepsy after a study of several peculiar cases of hysteria. The first case was that of a girl of sixteen, with tubercular heredity, who had previously had enlarged cervical glands, diarrhea and ascites. She entered the hospital with a suspicion of trouble at the right pulmonary apex, irregular fever and decided pain and tenderness over two vertebræ, increased on motion and jarring. The general neuropathic condition favored "spinal irritation" rather than caries, until she began to have headache, vertigo, vomiting, a staggering gait and a slight optic neuritis with ankle clonus. Later, typical hysterical attacks with all of Charcot's characteristic phases and hysterical stigmata led to a correct diagnosis of hysteria, and by isolation and proper treatment she was cured. A second patient had attacks of transitory confusion, genuine attempts at suicide, classical hysterical stigmata (anesthesia, contracted visual field, changes in the reflexes, mastodynia, etc.), unilateral convulsions in which the pupils were dilated and did not react to light, and other attacks with complete loss of consciousness and subsequent amnesia. A third patient was attacked with acute hallucinatory confusion, and convulsive attacks beginning with maniacal excitement, hysterical stigmata during the attacks and disappearing after them, polydipsia and polyuria. Steffens reviews carefully the so-called distinctive symptoms of hysterical and epileptic attacks. The most important is usually considered to be the condition of the pupils, normal in hysteria and dilated and immobile in epilepsy. He finds, on the contrary, not only in the above case, but in a considerable number of others which were undoubtedly hysterical, and were observed by competent men, that the pupils did not react to light. Furthermore, he finds a certain number of cases of hysteria reported, in which one or both pupils did not react during the interval, or where the pupils were unequal. In epilepsy, on the other hand, the pupils sometimes react during the attack. In the hysterical attack, too, the patient sometimes falls suddenly so as to injure herself, and she may even bite her tongue. Sudden pallor, unilateral convulsions, complete loss of consciousness and amnesia were also noted in his cases, and they have been observed repeatedly by others. Hysterical attacks may be brief, and epileptic long; a case of an epileptic seizure lasting eight hours being reported in connection with the cases cited above. Hypnotism may have no influence upon the attack and, if there be no hysterical stigmata, a differential diagnosis is often impossible. Although not observed in his own cases, Steffens cites other cases in which there was incontinence of urine during an hysterical attack. Steffens concludes that both hysteria and epilepsy are caused by disease of the cerebral cortex, whose pathological basis is unknown, that the essential nature of the two affections cannot be distinguished, and that the same marked cause may act merely in different form and different intensity and persistence. In the same attack we may recognize characteristics which seem to be "purely hysterical" and others which seem "purely epileptic."

Parinaud[12] has studied the ocular troubles of hysteria. One of the most distinctive characteristics of hysterical amblyopia is its association with contracture of accommodation, which may determine other symptoms, such as monocular polyopia and micromegalopsia. A concentric limitation of the visual field is one of the most important features of hysterical amblyopia. When this is slight, we must also look for disturbances of accommodation to determine the existence of amblyopia. When central vision is also involved, there may be complete blindness, as great as that due to optic atrophy. The visual field is apt to be more contracted after an hysterical attack, and its extent may sometimes be modified by influencing the accommodation either by lenses or atropine. It may also be greater with moderate illumination than under a bright light, owing to the influence of accommodation. Cutaneous irritation, unless applied to an anesthetic area, may enlarge the visual field. In order to prove the existence of dyschromatopsia from contraction of the visual field alone, the contraction for white must be very marked. The perception of red is the last to be affected in hysterical dyschromatopsia, while it is the first to be affected in dyschromatopsia from tabes or alcohol. The field for red is sometimes greater in hysterical amblyopia than the field for white. Hysterical central scotoma is occasionally, though rarely, found. The acuteness of vision is rarely much diminished, although it is often better in a moderate light than in a bright light. Diplopia is always due to a disturbance of refraction. Even in absolute amaurosis the pupils still react to light. The ocular movements are usually well performed in spite of anesthesia of the conjunctiva and the cornea and the absence of the oculo-palpebral reflex. The lachrymal reflex is often preserved. There is never hemianopsia, and hysterical amblyopia is never attended with changes in the fundus of the eye, unless there be co-existing organic disease of the brain.

JUDGE ELLIOTT, in the Circuit Court, Milwaukee, recently decided that Christian Scientists were not liable to prosecution under the State Medical Law. The court ruled that the Scientists could no more be held for practising medicine when their means for healing was by prayer than could a minister who prayed at the bedside of the sick and received therefor a fee, either directly or indirectly. — *New York Medical Journal.*

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

Meeting of December 18, 1900, the president, Dr. Alfred Worcester in the chair.

Dr. F. S. Newell read a paper entitled

CHOREA DURING PREGNANCY.[1]

Dr. T. M. Rotch: It is evident that chorea may come from different causes, especially from shock or fright, as often shown in children. I could mention a number of such cases that I have seen. On the other hand, certain forms appear to be infectious, as shown by the endocarditis which often develops.

Dr. C. W. Townsend: The cases Dr. Newell spoke of, in which the children as well as the mothers had choreic movements, are interesting, as they would bear out the infectious theory. That so few of the choreas of pregnancy develop endocarditis or are associated with rheumatism is very different from what is the case with children, and suggests that they may be of a different sort, of hysterical origin for instance. I am also struck by the infrequency of cases of chorea during pregnancy as contrasted with its great frequency in children.

Dr. E. Reynolds: It seems to me that the chief point in practice is to remember that while mild cases of the chorea of pregnancy are very mild affairs that terminate with pregnancy, the severe cases, on the other hand, are practically hopeless and not affected by the termination of pregnancy, so that we should not allow a mild case to become severe, and in questionable cases should not defer the stopping of pregnancy too long.

Dr. G. J. Engelmann: I have looked upon the chorea of pregnancy as one of those reflexes to which more attention has been paid in these later years, and in writing on a kindred subject some time ago I paid especial attention to chorea. Since then I have seen two cases. To me they seem not due to anemia or as of infectious origin, but as neuroses — to be compared with the reflex chorea seen in connection with menstrual and pelvic disturbances in young girls, especially at the time of puberty. The per cent. of cases seen harmonizes with the period of growth of woman, being greatest at the establishment of menstruation and dropping to the minimum with the stopping of the menstrual flow. Lately I saw a very violent case in a young girl coming on with a violent menstrual disturbance, the result of a mental strain, which lasted three months. Her chorea ceased with the regulation of her menstrual life. I think that most of the cases occurring in connection with changes in the pelvic viscera, whether pathological or physiological, are reflex as they yield to the removal of the pelvic cause.

[1] See page 397 of the Journal.

Dr. Newell: My reading on the subject leads me to feel that a case which after a time grows worse, is almost always fatal.

Dr. M. H. Richardson read a paper entitled:

REMARKS ON ANESTHESIA — GENERAL, LOCAL AND SPINAL.[2]

Dr. D. W. Cheever: Personally I have never seen a death from ether, and although I have been in a number of tight places, only once has it been necessary to resort to tracheotomy. I have used it in many cases of heart disease. One cause of its good working in such cases, if the operation be short, is that at first ether is a stimulant, next best to alcohol, though after a time this effect grows more feeble. As to spinal anesthesia, what the reader has said about the apprehension on the part of the patient is very important on account of the depressing effect of fear on the vital processes if the operation is to be long and critical. I used to do tracheotomy without an anesthetic, for I thought it safer. In such cases if we are quick, I doubt if the child suffers more than it does from the partial suffocation inherent in the use of chloroform or ether. As regards the freezing mixtures, I have found them fairly satisfactory, but my feeling is that in a long operation we ought to put the patient to sleep on account of the shock.

Dr. Engelmann spoke of operations on the extremities under an anesthesia induced by strong alternating currents.

Recent Literature.

Evans's Obstetrics. A Pocket Textbook of Obstetrics. By David J. Evans, M.D., Lecturer on Obstetrics and Diseases of Infancy in McGill University Faculty of Medicine, Montreal. In one 12mo. volume of 409 pages, with 149 illustrations, partly in colors. *Lea's Series of Pocket Textbooks.* Edited by Bern B. Gallaudet, M.D. Philadelphia and New York: Lea Brothers & Co.

This book is really more than its name, that of a "pocket textbook," would imply, in that the author has produced a creditable work on obstetrics of moderate size and completeness for the use of the medical student. The difficulty of condensing the subject of obstetrics into a small textbook without sacrificing important subjects and necessary details is at once apparent and the author has, we believe, done very well. The book is well written in a clear style, although necessarily much abbreviated, yet the essential points are all taken up and treated in a way sufficiently elaborate to give the average young student a good preliminary knowledge of the subject. The directions for treatment are given in a direct manner and conform, as far as the author goes, with what is generally accepted as proper treatment at

[2] See page 391 of the Journal.

the present time. There are no features in the book which are essentially new, but as a condensed volume for students it is above the average of such works, while it is not comprehensive enough for a complete textbook, or as a reference book for the practitioner.

Diseases of the Anus and Rectum. By D. H. GOODSALL, F. R. C. S. (Eng.), Senior Surgeon (late House Surgeon) to St. Mark's Hospital for Fistula and other Diseases of the Rectum; Senior Surgeon to the Metropolitan Hospital, and W. ERNEST MILES, F. R. C. S. (Eng.) Surgeon (outpatients) to the Gordon Hospital for Diseases of the Rectum; Assistant Surgeon to the Cancer Hospital, Brompton; late Senior Assistant Demonstrator of Anatomy at St. Bartholomew's Hospital Medical School, and House Surgeon to St. Mark's Hospital for Fistula and other Diseases of the Rectum, etc. In two parts (illustrated). Part I. London, New York and Bombay: Longmans, Green & Co. 1900.

This Part I of "Diseases of the Anus and Rectum" consists of chapters upon the Anatomy, General Diagnosis, Abscess, Ano-Rectal Fistula, Recto-Urethral, Recto-Vesical, Recto-Vaginal Fistulæ, Sinus over the Sacrum and Coccyx, Anal Fissure, and Hemorrhoids or Piles.

The authors have given an excellent description of the different diseases about the anus and rectum and have illustrated these conditions by selected cases from their case books. The illustrations are, as a rule, good. They are rather gruesome and are frequently extreme examples of a condition.

The book is one that can be turned to for sound, judicious advice in the treatment of these common affections. The binding of the volume is excellent.

Oral Sepsis as a Cause of Septic Gastritis. "Toxic Neuritis," and other Septic Conditions. With illustrative cases. By WILLIAM HUNTER, M.D., F.R.C.P., Senior Assistant Physician, the London Fever Hospital, etc. London, Paris, New York and Melbourne: Cassell and Company, Ltd. 1901.

This small volume of 30 pages is a bound reprint of an article which appeared in *The Practitioner* for December, 1900, and which has already been noticed in our editorial columns. The title describes the scope and object of the pages. It is an interesting, and on the whole, convincing discussion of the possible importance of septic mouth conditions in the production of various general disorders. It should prove profitable reading to practitioners in any department of internal medicine.

SUTURE OF THE HEART.— According to a report in the daily press the pericardium was opened and a stab wound into the cavity of the left ventricle of the heart closed by three sutures, in a case at the St. Louis City Hospital. The patient lived twenty-four hours.

PATHOLOGY OF THE JEWISH RACE.

THE relative predisposition of races and peoples to disease in general and to certain diseases in particular is a subject which has not received the study it deserves. With our growing interest in the all-important problem of immunity, we may easily see how essential is the accurate determination of race susceptibility to disease. Various observations and statistics of importance have from time to time appeared, but it is clear that deductions of scientific value cannot be made until a very large number of data are collected and carefully tabulated. Dr. Maurice Fishberg of New York has recently rendered a valuable service in the publication of a statistical paper appearing in the *New York Medical Journal* for March 30th and April 6th on "The Comparative Pathology of the Jews."

It is a matter of common knowledge that the Jews are both a very hardy race, capable of much endurance, and also peculiarly susceptible to certain disorders. Fishberg has analyzed available figures in great detail regarding the longevity of the Jews in various parts of the world, and has formulated statistics regarding various diseases. It is somewhat surprising that in spite of the fact that the Jewish population of the United States is at present estimated to be 1,058,135, no careful study of their racial peculiarities from a strictly medical point of view has been made. In Europe it has been found that the Jews live, on an average, considerably longer than Christians, showing a lower death rate, and an excess of the number of births over deaths. This occurs in spite of the fact that the Jews show a smaller marriage rate, and produce fewer children by each marriage than do Christians. What statistics we have for the United States go to show the same facts. The Jewish population is kept up because of the smaller infant mortality. Fewer are born, but more reach maturity.

The statistics regarding disease susceptibility are of very great interest, though still often difficult of interpretation. It has been found that tuberculosis, pneumonia, nephritis, typhoid fever, malaria and epidemic diseases are less prevalent among the Jews than among Christians. A certain immunity has been observed to plague, smallpox (possibly on account of greater willingness to submit to vaccination), typhus, intermittent fevers, epidemic dysentery and cholera. For example, during a cholera epidemic in Budapest, in 1851, the mortality among the Christian population was 1.85% as against .257% among the Jews, being seven times less. More recent statistics, however, seem to show that the immunity to contagious diseases is now not observable. Tuberculosis remains far less fatal among the Jews than in other races. Interesting figures are those taken from a study of the mortality in one of the most densely inhabited regions of New York City for the six years ending May 31, 1890. It appears that during that period the mortality from consumption reached, among the Irish, 19.44% of the death rate due to all other causes; among the Germans, 14.12%; among the English, 13.04%; among the Russian and Polish Jews, 5.76%. Alcoholism and syphilis are relatively infrequent among the Jews. Gonorrhea, however, appears about equally prevalent among Jews and Christians, which goes to show that freedom from syphilis is not due to greater chastity. Diabetes, on the other hand, is a disease to which Jews are, from the observations of many trustworthy observers, particularly predisposed. The same appears to be true of diseases of metabolism; for instance, gout, gall-stones and nephrolithiasis, chronic rheumatism, some forms of neuralgia and migraine, asthma, pulmonary emphysema, varicose veins, and especially hemorrhoids, arteriosclerosis, and some diseases of the skin. Finally, some authors state that blindness, color blindness, myopia, trachoma, glaucoma and almost all the skin diseases, are more frequent among the Jews than among the non-Jews.

The most conspicuous fact, however, regarding the diseases of the Jew, is the instability of his nervous system, a fact possibly associated with the peculiar stress to which he has been exposed for centuries, as suggested by Oppenheim. His words are:

> The nervous derangements which are the effect of psychic trauma explain to some extent the reason why the Jewish race—after being persecuted and oppressed, mostly only tolerated among the nations, living in peace for short times only, and then again tormented—is suffering in such immense numbers from the neuroses and psychoses, and particularly hysteria.

The organic derangements of the nervous system are apparently not more frequent among the Jews. Minor concluded that this was due to the fact that syphilis and alcoholism were much less common than among Christians.

Fishberg draws the following general conclusions from his study:

> The death rates of the Jews, at all ages, are relatively and absolutely lower than those of the people among whom they live. The marriage rates and birth rates of the Jews are smaller than those of the Christians. The Jews die less often than their neighbors from many of the infectious diseases, particularly epidemic cholera, smallpox, and tuberculosis. Syphilis and alcoholism, and also diseases due in great measure to their poisons, are comparatively rare among the Jews. Diabetes is very frequent among the Jews. All the functional neuroses and psychoses, particularly neurasthenia and hysteria, occur more frequently among Jews than among non-Jews; while all the organic nervous diseases, as tabes, general paralysis, etc., are less frequent, commensurate with the infrequency of syphilis and alcoholism among them. Blindness, color blindness, trachoma and glaucoma, and also varicose veins, particularly hemorrhoids and hernias, are very frequent among Jews. All these peculiarities in the comparative pathology of the Jews are not due to any ethnic, "biostatic," or racial characteristics of a purely anatomical or physiological nature in relation to non-Jews. They have their origin in the past history of the Jews, in their habits of life, and in the fact that syphilis and alcoholism have but rarely been seen among them. Where the Jew is commingling with his Christian neighbors and adopts their customs and habits of life, he sooner or later loses his "racial characteristics," and his comparative pathology presents no special peculiarities.

INSTRUCTIVE DISTRICT NURSING ASSOCIATION.

The fifteenth annual report of the Boston Instructive District Nursing Association has appeared. It is a small pamphlet, unpretentious in appearance, and its perusal would hardly give one an idea of the work being done by the organization which it represents. Nursing at best, when the glamour and romance have worn off, is not an easy or pleasant employment. The surroundings of a large hospital, the excitement attendant upon the care of patients seriously ill, surgical operations and all the circumstances of active routine, no doubt do much to palliate the unpleasantness of it all. The real test comes, however, when nurses are thrown on their own responsibility, and, without the satisfaction of companionship, are obliged to carry out the details of their professional work. Above all others, the district nurses have nothing to fall back upon but a sense of duty performed, and the feeling of satisfaction which comes with the relief of conditions of distress. There is absolutely no poetry in this; it is simply the hardest sort of work, done almost without recognition under the most difficult possible circumstances. These nurses, of whom there are now fourteen, not only care for the sick poor in their homes, but also instruct the

families they visit to take better care of themselves. The daily routine is as follows: the nurse meets the physician of her district each week day, generally at the place where the calls are left. She usually visits the new cases with him and the old cases which she thinks need his attention, but sometimes she makes the round of visits alone, after obtaining his written or verbal instructions. The rest of the day the nurse spends in visiting old cases, and in revisiting those new cases which need her care.

This is neither exciting nor romantic, but much more important. It is a system which is undoubtedly doing a vast amount of good in the most unassuming possible way. The women who undertake this work accept a life of real self-sacrifice, unalleviated by popular recognition, which ordinarily makes nursing, or any other calling, possible.

MEDICAL NOTES.

COLORADO MEDICAL LIBRARY ASSOCIATION.— The eighth annual meeting of this society was held at Denver, March 20th. The secretary, Dr. Carroll E. Edson, reported that 770 volumes had been added to the library, and that donations had been received from the Denver and Arapahoe Medical Society, of $150; and from Dr. John Boice, of 200 bound volumes of periodicals. The president, Dr. Henry Sewall, spoke on the needs of the library. Dr. Leonard Freeman was appointed to consult with the authorities of the County Hospital regarding some arrangements whereby the resources of the hospital for medical literature might be made available for the Association, and whether a fee on attendance on clinics could be collected from medical students, said fee to be applied to the purchase of medical journals. The election of officers resulted as follows: Dr. Charles D. Spivak, President; Dr. Edward Jackson, Secretary and Treasurer, and C. R. Dudley, Librarian.

A NEW APHRODISIAC. — The latest addition to the list is aphrodisiac yohimbin, the active principle obtained from a plant growing in equatorial Africa. Experiments have been made with this product on frogs and rabbits, and it is stated to produce marked hyperemia of the sexual apparatus. On this ground it is recommended for the treatment of sexual neurasthenia, and also in albuminuria. The ground for its use in the latter condition would seem decidedly uncertain.— *Medical Press and Circular.*

CRITICISM OF THE PRESBYTERIAN HOSPITAL OF PHILADELPHIA.— The Presbyterian Hospital of Philadelphia is being severely criticised in the daily press for refusing admission to a colored woman in labor, on the ground that the hospital did not receive maternity cases. The woman was delivered in the patrol wagon while on the way to the Philadelphia Hospital.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, April 24, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 61, scarlatina 37, measles 120, typhoid fever 7.

DEATH OF A CENTENARIAN.— Mrs. Sallie Batchelder died in Peabody, Mass., on April 22d at the age of 107. She was born in Chichester, N. H., August 8, 1794. She was the third of a family of fourteen children, of whom two sisters lived to be 93, and two brothers who were twins lived to the ages of 84 and 88 years.

SMALLPOX IN A RAILWAY TRAIN. — It has been extensively reported in the daily press that a woman suffering from smallpox and under the care of a Christian Scientist, travelled by train recently from New York to Southington, Conn., and was driven from the train to the residence of her father in a hack. The next morning the health officer was called in and the character of the disease discovered. As it is stated that the eruption on the forehead had appeared before the patient left New York, it would seem that this exposure of the public would have been avoided by calling in a physician.

NEW YORK.

THE ASSOCIATION FOR THE ADVANCEMENT OF PHYSICAL CULTURE. — The twelfth annual convention of the American Association for the Advancement of Physical Culture was held in New York on April 18th, 19th and 20th, Dr. Dudley Allen Sargent, of Harvard, presiding. In a paper on "The Need of Physical Training in Our Public Schools," Dr. Frederick J. Simpson, of Hartford, expressed the opinion that the neglect of the physical well-being of children attending school has resulted in an increase in insanity and a decrease in the birth rate throughout the United States. He advocated that in the education of the young less time should be devoted to study and more attention given to physical development. In a paper on "Ideals of Physical Training," Dr. Sargent deplored the practice of college athletes to devote all their energies to some special line of powers, instead of striving for the symmetrical development of their bodies. It is not, he said, a runner, jumper, boxer, oarsman or gymnast we would produce, but the highest type of physically perfected man. The breakdowns of athletes so frequently noted after they had com-

menced their life work he attributed largely to the neglect to keep themselves in condition. Dr. J. H. McCurdy, of the Young Men's Christian Association of Springfield, Mass., read a paper in which he gave the results of an extended series of observations on the effect of muscular effort on the blood and on blood pressure. Moderate exercise, he had found, causes an increase in the red corpuscles and a strengthened pulse, while exercise carried to excess reduces the number of red corpuscles and the tone of the pulse. Dr. Franz Boas, of Columbia University, was chairman of the Section on Anthropometry, in which papers were read by himself, Dr. Sargent, Dr. H. G. Beyer, of the United States Naval Academy at Annapolis, Dr. J. McK. Cattell, of Columbia, and Dr. Edward Hitchcock, of Amherst.

Equitable Enforcement of Medical Claim. — Dr. J. F. Sherman has finally succeeded, after prolonged litigation, in securing the application of a portion of a testamentary trust fund, provided by the late Francis N. Skuse for the support of his son, toward the payment of his (Dr. Sherman's) claim for medical services rendered the beneficiary upon his own request. The Court of Appeals, affirming the claim of the Appellate Division of the fourth department of the Supreme Court, holds that such a claim may be enforced in equity to the extent of the unexpended income in the hands of the trustees applicable to his support, when it appeared that the beneficiary had become insolvent, and it did not affirmatively appear that the trustees had furnished him with all that was necessary in respect to medical attendance. Under such circumstances, the court held, it might be assumed that the services were rendered with the knowledge and tacit consent of the trustees. The trustees might be regarded as mere custodians of the unexpended income in their hands, which it was their duty to apply to the payment of necessaries furnished to them for the beneficiary, or to the beneficiary himself with their knowledge and consent; and which equity would regard as having been so applied, the court simply directing a formal payment out of the fund, which the trustees should have made without such direction.

Christian Science and Osteopathy at Albany. — The Legislature has adjourned without passing the Anti-Christian Science bill. While this is a matter of regret, the community is to be congratulated on the fact that it also failed to pass the bill to license osteopaths, which would have flooded the State with quacks.

Appropriation for Craig Colony. — Governor Odell has approved the act appropriating $125,000 for improvements at the Craig Colony for Epileptics.

Medical Men in the Revolution. — At the celebration of the 126th anniversary of the Battle of Lexington by the Society of Sons of the Revolution, at Delmonico's, Dr. Sidney H. Carney, Jr., read a valuable paper on "Medical Men in the Revolution."

Christian Science. — In a recent paper before the Baptist Ministers' Conference, denouncing Christian Science, the Rev. Albert G. Lawson incidentally compared the name of the sect to that of the guinea pig, an animal which, he said, does not come from Guinea and is not a pig.

Diphtheria in the Bronx. — On account of the prevalence of diphtheria in the vicinity, the public school, and the parochial and Sunday schools at High Bridge, Borough of the Bronx, have been ordered closed by the Board of Health.

Miscellany.

THE SANITARY CONDITION OF HAVANA.

Major W. C. Gorgas, the chief sanitary officer of Havana, in his report to the Adjutant General, accompanying the vital statistics for the month of March, calls attention to the continued excellent sanitary condition of the city as shown by the general death rate. The general death rate, 26.28, it will be seen, is considerably lower than that of any March since 1889. The lowest previous rate for the preceding eleven years being that of 1893, when we had 27.60; the highest that of 1898, the last year of Spanish occupation, when we had 78. It will be seen from this, that we have had a steady decrease since the American occupation, and that we compare favorably with many other of the larger cities of the world.

According to Marine Hospital reports, Liverpool, for the week ending February 23, 1901, with a population of 668,645, had 338 deaths, being a death rate of 26.26; Dublin, for the week ending February 16, 1901, with a population of 349,594, had 235 deaths, which gives a death rate of 34.84 per thousand; Marseilles, for the month of January, 1901, estimated population 447,344, deaths 1,181, giving death rate 31.20.

The number of deaths for March is considerably larger than that for February, due to the increased number in the diarrheal diseases of children, and an increase of pulmonary troubles generally. As these causes effect the Cuban population mostly, it will be seen that the increase is entirely among the Cubans. The Cubans in February, 1901, had 305 deaths, and in March, 1901, 444.

Particularly attention is called to the condition of the city with regard to yellow fever. The report shows 4 cases and 1 death. The only two years since 1889 showing as small a number of deaths as this were 1892 and 1899, when there was 1 death in March for each of these years. Of these 4 cases reported in March, 1901, only 1 took

sick during March, the other 3 were taken sick during the latter part of February, and remained over into March. In 1900, during March, there were 11 cases and 4 deaths.

Previous to the year 1899, no record was kept of the number of cases, so that no comparison can be made. As a matter of fact, there was only 1 case of yellow fever in Havana since the 1st of March, and since March 23d the city of Havana has been entirely free from that disease. This is the first time this has occurred since June, 1899. There were two occasions in 1900 when the city went for a few days with no fever, but none since the time mentioned that it has been free from fever as long as at the present. Major Gorgas feels very much encouraged at the prospects for the summer.

He thinks the present freedom from fever is in part due to the systematic and extensive way in which they have been killing the mosquitoes for the last month. He has the greatest hopes of destroying the foci as they appear by systematically killing the mosquitoes over a large area around each focus as it occurs.

He is inclined to think that they have been free from fever for a longer time than has ever occurred in Havana before. Our records show longer periods in which no fever was reported in the early part of the year 1899, but at that time physicians had not learned to recognize the milder types of yellow fever, and were much less careful about reporting them, so that a case of yellow fever, which is now promptly recognized and reported, would then have been passed over.

The condition with regard to smallpox is equally satisfactory, and, while this disease is occurring in every part of the United States, in Havana there has not been a single case since August.

On March 3d, the examination of sputum for tuberculosis was begun, and during the month 70 examinations were made.

The sanitary authorities certainly deserve congratulation on the excellent showing made for the enlightened methods of sanitary administration introduced by the medical department of the U. S. army in Havana. The good health of the city is certainly a definite result of the American Protectorate, and in marked contrast to the conditions which prevailed under the Spanish Régime.

Correspondence.

FORMALDEHYDE GAS IN DIPHTHERIA.

BOSTON, April 15, 1901.

MR. EDITOR: — In a short communication which appeared in the JOURNAL, Vol. CXXXVI, No. 23, June 10, 1897, I called attention of the profession to the use of formaldehyde gas in the treatment of diphtheria, especially in cases in which the disease is located in the nasal cavities or their vicinity, and particularly in children. The plan then adopted consisted in placing the patient temporarily in a small room, the air of which was permeated with an uncertain amount of the vapor produced by the clumsy lamp which was the predecessor of the improved apparatus of today. I was surprised to find that a tender child could not only breathe the air thus charged with formaldehyde gas, which was very irritating to the eyes, nose and throat of the attendants, but that after a long persistence of the diphtheria bacillus in the secretions of the nose, the cultures rapidly became less abundant, and within a few days were negative. This was verified by control.

Since that time, I have continued to employ this method of treatment with most satisfactory results. The only material variation in its use being the entire abandonment of all forms of apparatus for the generation of free formaldehyde gas, by the substitution of a dilute solution of the gas in water, which is now to be easily obtained under a variety of names; formaldehyde, formaline, etc., all of which I suppose to be the same substance placed upon the market by different manufacturers. I have observed no variation in the effect produced.

Further experience has proved that the exposure of the patient to the continuous inhalation of the vapor of formaldehyde is a more efficacious form of germicidal treatment than that previously advocated in the cases earlier reported. I have found that the patient with diphtheria may remain constantly for days or even weeks in an atmosphere which is saturated with the vapor of formaldehyde derived from the evaporation of a 2 % solution of the formaldehyde of trade, not only without detriment, but absolutely without discomfort. Towels saturated with this solution are suspended in various parts of the room, and a double sheet arranged in the entrance to the sick room, where continual ventilation affords a constant supply of fresh air, which by its contact with the towels becomes charged with a most potent disinfectant. Each inspiration thus carries with it a volume of formaldehyde reaching to the utmost circulation of the air within the lungs, and the intervening respiratory tract is constantly bathed with an ebb and flow of the gas.

It is not necessary to present an array of cases in support of the treatment here advocated, but perhaps two may be mentioned. The first is that of a frail rachitic girl afflicted with organic valvular lesion of the heart, due probably to longstanding chorea from which she still suffers. In November last she was prostrated by an attack of diphtheria, of a very severe character. Antitoxine was freely employed at once, and on the succeeding day, and the culture sustained the provisional diagnosis. The strictest precautions as to local disinfection, isolation, etc., were rigidly carried out. The seat of the local lesion was upon the roof of the mouth, the soft palate, and the pharynx, chiefly on the right side. A large slough was formed, which was later discharged. Nourishment returned through the nose, and there was severe pain in the ear, and albuminuria soon appeared. This was followed by almost complete bilateral loss of sight, without physical ocular lesion. Somnolence and stupor succeeded, the child could take hardly any nourishment, an acrid and extremely offensive discharge flowed constantly from both nostrils, and the patient showed signs of cardiac failure; the skin became waxy and dull, the prostration increased, and death seemed imminent.

In the meantime the throat had become clear of bacilli, but they were still found in large numbers in the discharge from the nostrils, which were so occluded as to render respiration by these channels impossible. At length, however, there was a free discharge of thick sloughing matter from the nose, and it was possible for the child to breathe by this route. Applications of soothing character had constantly been made to the nostrils, but had seemed to have no effect until the free passage of the air loaded with formaldehyde was possible, when the bacilli soon disappeared and the Board of Health declared the disease at an end. The other concomitant symptoms slowly subsided, and the child has recovered her former state of health. The final disappearance of the bacilli corresponded so closely to the freeing of the nasal passages that the effect seemed more than a coincidence. There were no symptoms of poisoning, nor even of discomfort from the prolonged

breathing of formaldehyde gas, and no bronchial irritation remained after its use.

The second case which I will mention affected a teacher in a public school, who has long been subject to recurrent attacks of "erysipelas" [from her own statement]. The cause of her present illness was really erysipelas, located upon the nose, face, lips, and extended later to the neck, chin and to the border of the hair, where it was arrested by a fence of contractile collodion, across which it did not pass. On the second day, a culture was taken from her nostrils with the desire to obtain the bacterium of erysipelas. What was my surprise to find an almost pure culture of diphtheria germs, some of them of exquisite form, for the opportunity of seeing which, I am under great obligation to Dr. Hill and his assistant at the laboratory of the Board of Health. Formaldehyde inhalation was at once adopted. In this patient, also, the nostrils were closed by the great swelling caused by the erysipelas. There were in all the course of the case absolutely no clinical symptoms of diphtheria, but the bacilli continued present in the discharge. When the erysipelas had so far subsided as to allow nasal breathing, the discharge at once became less, and in a short time the bacilli disappeared from the cultures, and the patient soon entirely recovered. In this case there was no suspicion of infection from diphtheria, and it is an interesting question how long this patient may have been carrying active infection into her schoolroom without any appearances of the disease in her own person.

The above and other similar experiences have convinced me that, in cases of diphtheria, we have in the vapor of formaldehyde a means of obtaining a germicide action upon the surfaces chiefly affected by the bacilli, which is obtainable in no other way; and which may be thus continuously exposed to efficient disinfection by the most active parasiticide at present known. I think it doubtful if it has any action upon the toxin already formed in the course of the disease, but its effect has uniformly been to destroy the germs upon the surface of the mucous membranes. A chief consideration for its employment is found in its absolute absence of danger to the patient, even when the air of the sickroom is almost intolerable to one entering the apartment. This quality would certainly be of service in cases treated at home; without trained nurses or the benefits of hospital wards. The protection to others is much greater if formaldehyde is used in the care of the patient. I have not been able to find any record of the use of formaldehyde in this way, which antedates my former communication, and only few allusions to the subject in any way. The only reference of this kind which I have seen was kindly given me by Dr. Hill, from the "Tenth Annual Report of the State Board of Health of Maine," issued July 27, 1898, through its secretary, A. G. Young, M.D., as follows. "While formaldehyde gas is irritating to the eyes and nose, the general testimony of those who have worked with it and have been much subjected to its influence is that no permanent ill results follow ordinary exposure to it."

"After disinfection of rooms with formaldehyde, no poisonous substance remains. The odor is comparatively transient and but slightly disagreeable. A temporary airing renders the room habitable again."

"Various authors have recommended formaldehyde as an agent for the local treatment of diphtheria, whooping cough, influenza, tuberculosis and other diseases by inhalation or otherwise."

Dr. C. B. Smith states that he is "satisfied that constant breathing of formaldehyde vapor had been a valuable aid in preventing extension of membrane . . . although antitoxine had been used early and in considerable doses to neutralize the toxin."

Dr. Hill has suggested that the constant inhalation of formaldehyde might be of service in tuberculosis, especially in the laryngeal form of that disease, in certain affections in or about the tonsils, nasopharynx and about the eustachian tube. I think it might be employed in proper dilution as a local application to some of the forms of destructive or malignant growths in the same region. Its action is that of drying or mumifying the tissues to which it is applied, with destruction of the superficial structures. It would also seem to be appropriate to the treatment of scarlet fever, ozena or other infective conditions of the throat, pharynx and nose, in relation to the extension of the disease to the middle ear, with all that this implies.

Should the claim here presented as to the influence of formaldehyde gas as a valuable aid in the treatment of diphtheria in locations not accessible to topical applications be doubted, the favorable effect upon the surroundings of the patient should still lead to its employment. The putrid and almost insufferable odor which accompanies the severer forms of diphtheria is at once destroyed, vermin will not remain in its presence, and the care of the patient is rendered far less dangerous and immensely less disagreeable. Flies which penetrate to the sickroom have been observed to fall dead before reaching the opposite side of the room. This fact alone would seem to be a recommendation for its use from the increased comfort afforded the patient, particularly in cases which cannot receive the benefit afforded by treatment in hospital.

Yours respectfully,

ALBERT N. BLODGETT, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 13, 1901.

Deaths reported 2,876; under five years of age 876; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 652, acute lung diseases 445, consumption 333, diphtheria and croup 66, diarrheal diseases 49, scarlet fever 71, influenza 10, typhoid fever 34, whooping cough 24, measles 13, cerebro-spinal meningitis 15, smallpox 14.

From whooping cough, New York 10. Philadelphia 6, Pittsburg 4, Boston, Worcester, Chicopee and Medford

1 each. From cerebro-spinal meningitis, New York 7, Pittsburg 1, Brockton 3, Gloucester 2, North Adams and Pittsfield 1 each. From scarlet fever, New York 50, Philadelphia 6, Pittsburg 2, Boston 10, New Bedford, Malden and North Adams 1 each. From typhoid fever, New York 14, Philadelphia 5, Baltimore 1, Pittsburg, 9, Providence, Boston, Lowell, Chelsea and Clinton 1 each. From measles, New York 10, Boston 3. From smallpox, New York 11, Pittsburg 1, Boston and Fitchburg 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,999, for the week ending March 30th, the death rate was 19.7. Deaths reported, 4,450; acute diseases of the respiratory organs (London), 363, whooping cough 146, diphtheria 59, measles 120, fever 25, scarlet fever 34.

The death rate ranged from 13.0, in West Ham, to 29.7, in Plymouth; Birkenhead 14.0, Birmingham 23.4, Blackburn 17.6, Bolton 18.5, Bradford 16.6, Brighton 14.6, Bristol 21.5, Burnley 17.7, Cardiff 16.9, Croydon 12.8, Derby, 21.4, Gateshead 20.4, Halifax 17.1, Huddersfield 23.2, Hull 21.4, Leeds 18.7, Leicester 17.4, Liverpool 28.1, London, 18.4, Manchester 22.0, Newcastle-on-Tyne 23.2, Norwich 21.5, Nottingham 22.9, Oldham 20.1, Portsmouth 18.1, Preston 17.8, Salford 22.4, Sheffield 20.3, Sunderland 21.7, Swansea 18.0, Wolverhampton, 19.6.

METEOROLOGICAL RECORD.

For the week ending April 13th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The annual meeting will be held at the Medical Library Building, 8 The Fenway, on Saturday, April 27, 1901, at 8 P.M.

Papers: "The Teaching of Therapeutics," by Dr. Franz Pfaff.

Discussion by Drs. F. C. Shattuck, J. J. Putnam, T. M. Rotch, F. G. Wheatley, Edward Reynolds, E. O. Otis and R. W. Lovett.

Business: Report of the librarian and treasurer; election of officers; appointment of delegates to the annual meeting of the American Medical Association; appointment of a committee to consider the advisability of establishing an Academy of Medicine. Supper after the meeting.

HOWARD A. LOTHROP, Secretary,
H. L. BURRELL, President,
10 Marlborough Street.

SUFFOLK DISTRICT MEDICAL SOCIETY, CENSORS' EXAMINATION.—The censors of the Suffolk District Medical Society, officiating for the Society at large, will meet to examine candidates for admission to the Massachusetts Medical Society at 8 The Fenway, on Thursday, May 9, 1901, at 2 P.M.

Candidates should make personal application to the Secretary, and present their medical diploma, at least three days before the examination.

For further particulars apply from 2 to 3 P.M. to

HOWARD A. LOTHROP, M.D., Secretary.
10 Marlborough Street.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—The Surgical Section will meet at the Medical Library, 8 The Fenway, on Wednesday evening, May 1, 1901, at 8.15 o'clock.

Papers: "Strangulation of the Testis by Torsion of the Cord," by Dr. C. L. Scudder; "Report of Two Cases of Strangulation of Intestine by Bands," by Dr. J. W. Elliot; "Report of a Case of Intussusception," by Dr. F. G. Balch.

F. G. BALCH, M.D., Secretary.
279 Clarendon Street.

RECENT DEATHS.

GEORGE COGSWELL, M.D., M.M.S.S., died in Haverhill, April 21, 1901, aged ninety-three years.

BOOKS AND PAMPHLETS RECEIVED.

Massage in Raynaud's Disease (Symmetrical Gangrene). By Douglas Graham, M.D., of Boston, Mass. Reprint. 1901.

Two Unusual Cases of Surgery of the Trachea. By W. S. Jones, M.D., and W. W. Keen, M.D., of Philadelphia. Reprint. Illustrated. 1899.

Progressive Pernicious Anemia. By Alfred Stengel, M.D., of Philadelphia; Professor of Clinical Medicine in the University of Pennsylvania. Reprint. 1900.

Some Notes on the Treatment of Rheumatism. By Alfred Stengel, M.D., of Philadelphia; Professor of Clinical Medicine in the University of Pennsylvania. Reprint. 1900.

The Endowment of Medical Colleges. By W. W. Keen, M.D., LL.D., President of the American Medical Association at the meeting in Atlantic City, June 5, 1900. Reprint 1900.

Chronic Urethritis of Gonococcic Origin. By J. De Keersmaecker and J. Verhoogen. Translated and edited with notes by Ludwig Weiss, M.D. New York: William Wood & Co. 1901.

Aneurism of the Arch of the Aorta, with Rupture into the Superior Vena Cava. By Alfred Stengel, M.D., Professor of Clinical Medicine, University of Pennsylvania. Reprint. Illustrated. 1900.

Massachusetts Infant Asylum. Thirty-Fourth Annual Report of the Directors Presented to the Corporation at the Annual Meeting, February 19, 1901. Reprint. Brookline: The Riverdale Press. 1901.

The Feeding of Infants. Home Guide for Modifying Milk. By Joseph E. Winters, M.D., Professor of Diseases of Children, Cornell University Medical College. New York: E. P. Dutton & Co. 1901.

Some Remarks Upon Digitalis Treatment in Chronic Disorders of the Circulation, and Especially Upon the Continuous Use of Digitalis. By Medicinalrat J. Groedel, M.D. (Bad Nauheim). Reprint. 1900.

Hygiene and Public Health. By Louis Parkes, M.D., D.P.H., London University and Henry Kenwood, M.B., D.P.H., F.C.S. Illustrated. London: H. K. Lewis. Philadelphia: P. Blakiston's Son & Co. 1901.

A Review of the History of Cardiac Pathology, with Especial Reference to Modern Conceptions of Myocardial Disease. By Alfred Stengel, M.D., Professor of Clinical Medicine, University of Pennsylvania. Reprint. 1900.

Traumatisms Inflicted by Animals. By R. Harvey Reed, M.D., of Rock Springs, Wyoming, Division Surgeon Union Pacific Railroad; Emeritus Professor Principles and Practice of Surgery and Clinical Surgery, Ohio Medical University. Reprint. 1900.

Treatment of Prostatic Hypertrophy. By Parker Syms, M.D., Clinical Professor of Surgery in the University and Bellevue Hospital Medical College; Surgeon to Lebanon Hospital; Member of the New York Surgical Society; Member of the American Medical Association; Member of the New York State Medical Association. New York City. Illustrated. Reprint. 1900.

International Clinics. A Quarterly of Clinical Lectures and Especially Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose and Throat, and Other Topics of Interest to Students and Practitioners. By leading members of the medical profession throughout the world. Edited by Henry W. Cattell, A.M., M.D. Vol. I. Eleventh series, 1901. Philadelphia: J. B. Lippincott Company. 1901.

Original Articles.

CONTUSIONS OF THE ABDOMEN.[1]

BY CHARLES L. SCUDDER, M.D., BOSTON,

Surgeon to Out-Patients at the Massachusetts General Hospital; Assistant in Clinical and Operative Surgery, Harvard Medical School.

ACUTE abdominal emergencies command the attention of physicians and surgeons alike. The subject which I have the privilege of presenting for your consideration and discussion this evening, "Contusions of the Abdomen," embraces a highly important group of acute abdominal emergencies due to traumatism.

There being no external wound, the physician is first summoned. Upon him rests grave responsibility, for the mortality in these cases is very great — deplorably great. Many cases are fatal if left to themselves and the physician. Surgical intervention, to be successful, must be early, perhaps before a diagnosis is completely made. The physician must be on the alert to the proper interpretation of the signs immediately succeeding the trauma. Patients of this class, who are ignorantly watched, frequently die. Few, even with an hospital experience, meet many of these emergencies. It is for this reason that I have attempted to present this subject in a somewhat systematic fashion, that we may review the facts as they exist today in these important cases. It is impossible to present here, in brief space, all the evidence for and against the views expressed. The evidence presented in literature has been carefully studied, and the following observations seem reasonable in the light of our present knowledge.

INJURIES TO THE URETER.

Rupture of the ureter following a contusion of the abdomen is a rare injury. That it may happen has been demonstrated by the 2 reported cases of Poland and Mackenzie.

Rupture of the ureter is caused either by compression of the abdomen, forcing the ureter against the transverse processes of the third, fourth and fifth lumbar vertebræ, or by traction on the ureter, tearing it at its two most fixed portions. The two fixed portions of the ureter are a little below the pelvis of the kidney and at the brim of the bony pelvis. All ruptures are above the true pelvic brim. Tuffier's experiments and Poland's case confirm these observations.

Twenty-three cases are recorded in medical literature as rupture of the ureter following abdominal contusion. Ruptures of the pelvis of the kidney and of the kidney tissue proper have been improperly reported as ruptures of the ureter. Of the 23 recorded cases, 12 have some good pretension to being classified as injuries to the ureter proper. Of these 12 cases, 5 presented contracted ureters, associated with hydronephrosis following trauma. Five were very probably ruptures of the ureter, 2 cases proved without any doubt to have been cases of ureteral rupture.

The general symptoms of shock may be present. These may subside within a few hours. If no lesion of an abdominal organ complicates ureteral rupture, no very grave symptoms will appear. If, after the subsidence of shock, a little blood appears in the urine, it is evidence of injury to the genito-urinary tract. If the amount of blood is small, perhaps only an occasional tiny clot, the suspicion should be great of rupture of the ureter. If, along with this very slight and intermittent hematuria, there is a persistent pain in the side, the evidence for rupture of the ureter is still stronger. The pain may be associated with local tenderness over the ureter. Transient hematuria may easily be overlooked.

If the ureter is torn across, a retroperitoneal accumulation of urine will form. This tumor of urine and blood does not appear for several days. Upon its recognition the diagnosis of injury to the pelvis of the kidney or ureter can be made. This tumor can be palpated through the anterior abdominal wall. Seven days is the shortest time for the development of this retroperitoneal fluid tumor. It is impossible to distinguish clinically between a ruptured pelvis of the kidney and a rupture of the ureter.

If there is complete prolonged obstruction of the ureter, an atrophy of the kidney will occur. If there is partial obliteration of the ureter, and the patient lives, after months or years, a renal abscess, a pyo- or hydronephrosis or a cystic kidney will form.

Wounds of the ureter have very little tendency to spontaneous repair. Wounds of the kidney, on the other hand, heal without great extravasation of urine.

If there is no associated serious injury, and if the peritoneum is uninvolved near the ruptured ureter, there is no especial danger to life in these cases. If the peritoneum is involved, extravasation of urine and blood into the peritoneal cavity adds greatly to the gravity of the accident. It is characteristic, then, of injuries to the ureter that the symptoms which will assist in localizing the lesion are often delayed in appearing. The delay in some cases may be due to the fact that the injury to the ureter is primarily a bruising, which subsequently ruptures through necrosis of the ureteral wall.

As yet no surgical treatment has been attempted upon the ureter itself. When cases are seen early after the injury, immediate suture or anastomosis is the ideal treatment.

After infection has occurred in these cases of retroperitoneal accumulation of urine and blood from ureteral rupture, it is extremely difficult to find the rupture in the ureter. Even if it could be found easily, it is questionable whether success would attend any attempt at anastomosis under the existing septic conditions. Lumbar incision and drainage is indicated in these cases. Nephrectomy should be the secondary operation. Puncture and aspiration of these retroperitoneal cysts

[1] Read before the Surgical Society of the Buffalo Academy of Medicine, April 2, 1901.

is a measure of doubtful curative utility, although it has been successful in a number of cases.

RUPTURE OF THE URINARY BLADDER.

Since the monograph by Rivington, in 1884, nothing more than isolated cases and groups of cases has appeared in medical literature upon this subject.

Rupture of the urinary bladder is infrequently seen. It follows some kind of injury to the lower abdomen. It is frequently met with in connection with fracture of the pelvis. Uncomplicated cases are unusual. The mortality is large. The rupture in these uncomplicated cases takes place at the posterior and upper part of the bladder and in a vertical direction, if the rupture is intraperitoneal. If the rupture does not pass entirely through the muscular wall of the bladder at the time of the accident, no very acute symptoms will appear. At the time there will be a delay in the appearance of these symptoms until the necrosis of the bladder wall completes the perforation. Hogerstedt reports a case in which the delay was three days.

The following initial symptoms of rupture of the bladder are common to both the intra- and extraperitoneal forms, namely: Pain in the abdomen referred to the hypogastrium or umbilicus; a feeling of something having given away within the belly; difficulty in standing and walking; a certain amount of shock or depression; nausea; rectal tenesmus; temporary relief to the desire to make water, followed by a more urgent desire, but inability to do so; catheterization, bringing away blood or bloody urine or nothing at all. The patient may come to the surgeon complaining of retention of urine, so-called. Suppression of urine if present may be reflex and does not prove a bladder rupture to have occurred.

It is sometimes difficult without laparotomy to distinguish between intra- and extraperitoneal rupture. The intraperitoneal ruptures are attended with the most severe symptoms of shock, and peritonitis appears usually after a few hours

A few cases have been recorded in which clear urine, not bloody, has been drawn by catheter and yet the bladder has been ruptured. The catheter may pass beyond the bladder into the abdominal cavity if rupture is present.

In extraperitoneal ruptures the symptoms of peritonitis will not be present unless the peritoneum has been injured by the violence which occasioned the rupture of the bladder or becomes involved secondarily, by urine under it or by infection through the sloughing sub-peritoneal tissues consequent upon extravasation of urine. Sooner or later, appear signs of septicemia.

Now, if the bladder is emptied by catheter and a measured quantity of warm boracic acid solution injected, if all injected water returns through the catheter, this is pretty good evidence that the bladder is intact. If there is intraperitoneal rupture the patient may feel the injected water enter the abdomen.

Walsham has once injected the bladder, following contusion of the abdomen, with air, as Keen has suggested. The escape of air into the general peritoneal cavity being recognized, it was concluded that an intraperitoneal rupture of the bladder existed, and such was found to be the case at operation. Free fluid in the abdomen will suggest intraperitoneal rupture. Unilateral hypogastric tenderness and tumor will suggest extraperitoneal rupture. Treatment should remove the extravasated urine, render clean the peritoneum or the extraperitoneal cavity, close the intraperitoneal bladder wound, if possible, and temporarily drain the bladder. Suture of the extraperitoneal bladder wound should not be attempted. If there is doubt as to whether the rupture is extra- or intraperitoneal, the abdomen should be opened. The Trendelenberg position and the rectal bag will facilitate the suture of intraperitoneal ruptures.

RUPTURE OF THE LIVER.

It is often associated with lesions of other organs. A blow upon the lower right thorax and falls from a height are the common causes of hepatic rupture. A very small wound of the liver may cause fatal hemorrhage. A large wound of the liver is, of course, most serious. Of 543 cases of injury to the liver more than one-half died within the first twenty-four hours of hemorrhage. Wounds of the liver have only a slight tendency to cease bleeding spontaneously. Usually the right lobe is torn upon its convex surface, and in an anteroposterior direction. The shock present is often out of all proportion to the hemorrhage.

Pain in the abdomen, both local and general, is severe and continuous rather than intermittent. The pain may radiate toward the umbilicus and the right shoulder. Jaundice may appear after a few days. It is rare before the second day. Bile may be found in the urine.

In the treatment of wounds of the liver, suturing, cauterization and tamponing have been successfully employed. Sutures may tear through the liver tissue, although often holding well. Tamponing will be of service in deep tears. Cauterization is adapted to superficial wounds.

The healthy gall bladder is rarely torn.

CONTUSIONS OF THE KIDNEY.

Maas's collection of 71 recorded cases of contusions of the kidney prior to 1878, combined with Spencer's collection of 118 cases reported between 1878 and 1896, make a total of 189 cases of what must be regarded as an unusual injury.

Rupture of the kidney due to trauma is unilateral; occasionally only is it bilateral. The rupture is rather constantly transverse to the long axis of the kidney, in the grain of its development, so to speak.

The following have been some of the accidents causing contusion of the kidney: Falls from a height striking the loin upon a blunt object like a beam, a fence rail, or a stone; a squeeze from a

moving car; compression of the abdomen by a heavy cart wheel; kicks by a horse.

The damage done may be a simple contusion of the kidney substance, a tearing of the capsule overlying the lacerated kidney, a rupture of the pelvis of the kidney, a tearing of the renal vessels, or a complete crushing of the kidney. Various combinations of these lesions may be found in any individual case. If the kidney is simply contused, hemorrhage will take place within the kidney capsule; if the renal capsule is torn, hemorrhage will occur into the perinephritic tissues forming a pseudo-hydro-hematonephrosis; if the peritoneum is torn, it is possible for both urine and blood to accumulate within the abdominal cavity.

Herzog finds that in falls and blows upon the lumbar region, the hilus of the kidney is torn, and that retroperitoneal hemorrhage is present. On the other hand, he finds that in crushes from in front, the kidney is torn anteriorly and crushed, and that hemorrhage usually takes place into the general peritoneal space. Keen has called attention to the fact of a greater frequency of intraperitoneal rupture of the kidney in childhood, as compared with that in adult life. This he thinks due to the late development normally of perinephritic fat tissue. In childhood the peritoneum lies directly in contact with the anterior surface of the kidney with no intervening fat tissue; hence the greater liability to involvement of the peritoneum in rupture of the underlying and contiguous kidney substance.

Hematuria is a sign of injury to the kidney. Of 189 cases of kidney subcutaneous injury, hematuria was absent in only 10 cases. In these 10 cases the absence of hematuria was occasioned by a clot in the ureter, a thrombosis of renal vessels, associated with considerable damage to the kidney substance, and a pre-existing stricture of the ureter. These are rather exceptional conditions, but they must be reckoned with. One case should be mentioned in this connection, that of Newman, in which, following a blow upon the loin, hematuria was present. In this instance no rupture of the kidney existed, but the history of the case determined that the hematuria was due to a pre-existing papilloma of the bladder.

Hematuria may be absent immediately after the accident and appear after several days.

Anuria sometimes follows an injury to one kidney, but is more likely to exist after an injury to both kidneys.

Pain in the region of the injured kidney is usually constant and pretty severe. It may radiate toward the groin.

In extreme laceration of the kidney, the force may have been so great as to cause lesions of other important organs, and all the evidences of kidney lesion may be so concealed as to render it impossible of recognition.

Hemorrhage and sepsis are the two dangers to be feared after rupture of the kidney. If the peritoneum is torn over the injured kidney, the hemorrhage is not restrained by the pressure of perinephritic tissues. The patient may show evidences of intra-abdominal hemorrhage. An immediate laparotomy and probably a nephrectomy will be necessary in order to check this hemorrhage.

Normal urine is not infective, but if the genito-urinary tract is opened into the peritoneal cavity, an infection atrium is present.

Hematuria is a very unsafe guide to the amount of hemorrhage that is going on. It is no criterion as to whether to operate or not. Hematuria is of value only as a diagnostic sign. It indicates only that the urogenital tract has been wounded.

It is possible that hemorrhage may occur to an alarming extent, entirely extraperitoneally. This will be indicated by signs of hemorrhage in general, and locally by a rapidly forming tumor in the loin which is usually palpable through the anterior abdominal wall, is dull on percussion and is independent of any change in the position of the body. Under the above circumstances immediate lumbar incision and a checking of the hemorrhage is demanded. Nephrectomy may prove necessary. If immediate laparotomy or lumbar incision is unnecessary, an expectant treatment is to be followed. If the extravasation of blood and urine extraperitoneally becomes infected, a lumbar incision and drainage, and possibly a secondary nephrectomy will be indicated.

The mild cases of kidney contusion demanding only expectant treatment and rarely operation, usually recover. Fortunately the mild cases are the most numerous. The graver cases do not recover without operation.

Statistics demonstrate that in primary nephrectomy the mortality is less than in secondary nephrectomy after sepsis is present. Therefore, the following is a wise course to pursue, namely: If there are severe or dangerous symptoms of either hemorrhage or sepsis present, operate in an exploratory way and be guided by circumstances as to whether a nephrectomy is done or not, remembering that the early nephrectomy is safer than the late one. If possible, one should not wait for sepsis to appear. Keetley,[2] in 1890, did a partial nephrectomy upon a lacerated kidney; the man recovered. Bardenheuer[3] resected one-third of the kidney and the patient recovered satisfactorily. This procedure of partial nephrectomy is one to be seriously entertained. Every particle of kidney tissue should be saved rather than to sacrifice any unnecessarily.

In packing the wound after nephrectomy, it should be remembered that several cases are recorded in which the gauze packing compressed the colon to such a degree as to cause intestinal obstruction. Israel has mentioned one such case. Before nephrectomy is done, the kidney of the other side should be palpated to be positive of its presence.

Whenever a nephrectomy is done for contusion of the kidney, the urine should be examined to determine the behavior of the remaining kidney. In nephrectomy for disease or new growth, com-

[2] Lancet, London, 1890, i, 134.
[3] Arch. f. klin. Chir., 1891, xlii, 371.

pensatory hypertrophy will have been established in the remaining kidney before operation. In nephrectomy for injury no such compensation exists, consequently, the effect upon the remaining kidney will be quite different from that seen in the first instance.

INJURY TO THE STOMACH.

The stomach wall is very elastic; it is protected by the ribs, the liver and the bowel. Rupture of the stomach, followed by the escape of stomach contents, is rapidly fatal. The anterior wall of the stomach is the location of most ruptures. One case is reported in which operation was done on the fourteenth day; a tear 4 centimetres long was found. The stomach contents had been walled off by local peritonitis. Recovery took place.

An incomplete separation and laceration of the mucous coat of the stomach is not uncommon. Ziegler[4] reports a cyst which formed in the anterior wall of the stomach, probably from a contusion of the upper abdomen. The cyst was drained and the patient recovered.

Guinard[5] reports a case of contusion of the abdomen; perforation of the stomach; suture; recovery. The perforation was in the lesser curvature near the pylorus, and was caused by a carriage wheel passing over the abdomen. Blackish vomitus and tarry stools and peritonitis existed.

A severe pain in the gastric region, lasting for a long time, associated with an anxious facies, some restlessness, nausea and the vomiting of blood, is strongly suggestive of stomachic rupture. In 6 out of 11 cases vomiting of blood was especially mentioned. In one instance this symptom was absent, and this proved to be a complete rupture near to the pylorus. Of 11 cases, not including those above, the longest period of life following the accident was fourteen hours.

RUPTURE OF THE INTESTINES.

The form of injury which produces an intestinal rupture is varied. Of 80 cases analyzed, 36 were from horse kicks; 23 from carriage wheel accidents; 13 from man kicks; 8 from spent shells. Violent and sudden percussion of the abdominal parietes is characteristic of all these forms of injury. The force is in each instance exerted over a comparatively limited area of the abdomen. A perpendicular blow is most harmful to the intestine. The small bowel is the seat of the lesion in 75% of all intestinal ruptures due to traumatism. The jejunum and the lower ileum are most often injured. These parts are at the junction of a fixed and movable portion of the bowel. There is usually more than one rupture found in the bowel. The rupture may be caused by a crush or by a bursting of the bowel. If by a crush, the wound in the peritoneum is usually smaller than that in the mucous and muscular coats. If by bursting, the wound in the peritoneum is larger than in the mucous and submucous coats.[6] There is a suggestion here in treatment. Be sure that the peritoneum covering all the lacerated mucous and muscular coats is reinforced. It may not be sufficient simply to close the peritoneal wound.

Usually the wounded bowel lies beneath the seat of the contusion of the abdominal wall. Rupture being most frequently due to a crush of the bowel against the lumbar spine, a search should be made, in operated cases, from the seat of the surface contusion back to the lumbar spine. The bowel lying in this line should be very carefully examined. In multiple lesions of the intestine, the lesions are superimposed and are more severe the nearer they are to the vertebral bodies.

If the visceral injury is merely a contusion of the intestinal wall, there being no immediate rupture, the appearance of serious symptoms of perforation may be delayed as much as five or ten days[7] until the contused area in the bowel has perforated, a necrosis following the contusion.

Contusion of the gut may lead to peritonitis, even when not so severe as to cause gangrene and perforation; the diminished vitality having allowed micro-organisms to penetrate the tissues and initiate an inflammatory process in the adjacent peritoneum.[8]

Rupture of the inner coats of the bowel, with some bleeding into the lumen of the bowel, often occurs when the peritoneal investment remains intact and no perforation occurs.

The researches of Cushing[9] and the lamented Livingood upon the bacterial flora of the intestinal tract are of very great importance in connection with wounds of this part. Peritonitis, following intestinal rupture, is dependent for its characteristics upon the bacterial flora of the canal at the site of the lesion. The prognosis of such peritonitis will be favorable proportionately with the scarcity and inocuousness of the micro-organisms which are present. In the upper portion of the intestinal tract, the bacterial flora is more scanty than in the lower portion. Wounds of the duodenum and jejunum are less fatal than of the lower ileum and colon. It is worthy of note in this connection that in health putrefactive changes, and consequently putrefactive organisms and their products, are absent from the small intestine.

Evidences of injury to the abdominal wall are usually wanting. There is no one unmistakable sign of rupture of the bowel. Shock may be either slight or profound, usually it is slight. It may be wanting. The army cases are valuable in this connection. A cavalry man, when kicked by a horse, exhibits often so little shock that he immediately remounts and rides some distance before being disabled and giving up. Many such cases have had a perforated bowel. The shock is independent of the severity of the blow.

Shock reduces sensibility to pain. Severe, persistent, localized abdominal pain, appearing either immediately after the injury, or after shock has

[9] Johns Hopkins Hospital Reports, vol. ix.

subsided, is the most important sign of rupture of the bowel. Early, frequent and uncontrollable vomiting is suggestive of rupture of the bowel. Tenderness, localized and persistent, is a very valuable sign.

Absence of liver dullness is suggestive of the escape of gas from a rupture of the bowel to between the liver and chest wall and diaphragm. Adhesion of the liver to the chest wall and to the under surface of the diaphragm would prevent this sign from being in evidence. Great tympanites may cause the liver dullness to disappear. Bloody stools are seen in some few cases of intestinal rupture. This is, however, an uncommon sign. The facial expression is often of very great importance. In intestinal rupture a serious, drawn appearance of the face is present, suggesting a grave difficulty.

Injury to the mesentery may, through hemorrhage, complicate a ruptured bowel. There is comparatively little bleeding from the torn edges of the intestinal wound. If intestinal rupture is suspected even, exploratory laparotomy should be done at once.

The fatality of uncomplicated concealed lesions of the intestine is very great. Cases of uncomplicated intestinal rupture group themselves roughly into three classes:

(1) Those in which shock, collapse and death follow each other in alarming rapidity. No surgical intervention is possible.

(2) Those in which the shock clears up in average rapidity and reaction appears. Some of the local signs become prominent, which have already been mentioned. Early operation will save many such cases.

(3) Those in which there is but slight shock, associated with vague signs of abdominal disturbance. The patient grows very gradually weaker. There is a question as to whether improvement is occurring or not. Meantime, sepsis is beginning in a most stealthy fashion, and even with a low temperature. These are cases to be operated early when it is first noted that improvement has ceased.

Persistent pain and tenderness and early vomiting should lead one to operate.

LACERATION OF THE SPLEEN.

A crushing injury or a blow to the lower left chest or to the upper left abdomen may cause a rupture of the spleen without evidence of external injury.

The signs of internal hemorrhage, together with the greater dullness in the splenic region following an injury to the left hypochondrium and lumbar regions, are sufficient to make a diagnosis of splenic rupture.

The dull area upon the left does not disappear upon turning the patient to the right side. The dullness upon the right side does vary as the individual is turned to the left. This is accounted for by the fact that the splenic blood having an unusually large proportion of colorless corpuscles coagulates rapidly. In Mixter's case (soon to be reported) the blood filling the abdomen was fluid, without much clotting. This is explained by the fact that the spleen was torn from its vessels and that the hemorrhage took place from the splenic vessels directly before entering the spleen.

The danger attending a ruptured spleen is hemorrhage. Most unoperated cases die from hemorrhage. A few cases which escape death from hemorrhage have a subphrenic abscess. There are a number of cases of rupture of the spleen where spontaneous recovery takes place, as shown by several post-mortem scars in spleens of persons who have previously suffered severe abdominal injuries.

Operative treatment may be: (1) Immediate splenectomy; (2) suture of the torn spleen; (3) or packing the torn spleen after cauterization. The choice of operation depends upon the condition of the patient and of the spleen. If the patient has lost much blood, if the spleen is large and extensively adherent, if the tear is favorably situated, suture is to be chosen. If, on the other hand, the capsule is thin and the spleen is soft and the tear is inaccessible, packing the wound is to be considered. Ordinarily, with a normal spleen, and particularly if it is much lacerated so that fragments are detached, splenectomy is the best operation. Hemorrhage is the paramount reason for operating. The loss of the spleen is unattended by such grave dangers as at first was thought probable. Up to date some 25 splenectomies have been done for subcutaneous rupture, with 13 recoveries. Dr. Mixter's case, yet unreported, will make 26 cases, with 14 recoveries and 12 deaths. Two cases were packed, with 1 recovery. One case was sutured, with 1 death.

There have been recorded several instances of unusual injury following contusion of the abdomen, noticeably rupture of the aorta, of the celiac axis, of mesenteric vessels, of the spermatic artery, of the inferior vena cava, of the portal vein, and of the gastroduodenalis artery. Rupture of the gall-bladder is recorded. Rupture of the rectus abdominis muscle is reported with fatal internal hemorrhage from a torn deep epigastric artery, the patient dying in six hours after the injury. Rupture of the diaphragm from external injury is recorded in but 3 instances.

INJURIES TO THE PANCREAS.

Rupture of the pancreas uncomplicated by injury to other organs is rare.

The reported cases of rupture of the pancreas may be grouped in two groups: Those almost immediately fatal and those not immediately fatal. Leith recorded 9 fatal cases of the first group. In only 2 of these 9 cases was the pancreas the only organ implicated. Death is due to hemorrhage. In the second group are those cases in which extensive cicatrization may be found post-mortem without any evidence of its presence during life, excepting that at some time severe abdominal injury was received. Pancreatic rupture is as yet unrecognizable. Signs of shock and collapse and internal hemorrhage following

upon sudden trauma to the epigastric region is presumptive of pancreatic hemorrhage. The trauma in the reported instances was directly backward and of considerable severity.

Here should be mentioned cases of "traumatic cyst" of the pancreas. In these cases, the earliest signs of trauma having cleared up after ten days or later, a second group of signs appears: Vomiting, indigestion, an epigastric tumor which occupies the umbilical, epigastric and left hypochondriac regions. It is highly probable under these circumstances that a rupture of the pancreas has occurred, and that a "pancreatic cyst" is forming, or that an epigastric cyst exists, having its origin from the ruptured pancreas.

Lloyd has discussed the relationship which exists between injuries to the pancreas and the accumulation of fluid in the lesser cavity of the peritoneum. It is very likely that many so-called cysts of the pancreas are accumulations of fluid blood and pancreatic secretion in the lesser omental cavity. That such cysts do develop after traumatism is now generally acknowledged. The peritoneum covering the anterior surface of the pancreas is the only barrier in a rupture of that organ to blood and pancreatic secretion, entering the lesser cavity of the omentum. Some 17 pancreatic cysts of traumatic origin are recorded. Early median abdominal drainage is the treatment commonly employed in these cysts.

GENERAL CONSIDERATIONS.

In approaching a case of contusion of the abdomen it is important to bear in mind several facts which are salient. The causes of the contusion should be investigated with great care; too often the effects manifest themselves by blind, delayed and insignificant signs. The resistance of the abdominal walls varies with age, the state of the health and with the amount of contraction of the abdominal muscles. Whether the injury, in other words, was expected or whether the abdomen was taken entirely unawares is worthy of consideration.

The traumatism to the abdominal wall may be severe, the resulting injury may be trivial and *vice versa*. A trivial blow may result in serious damage to intra-abdominal viscera. Usually, in these cases, the greater the force the greater is the injury. A diffused crushing blow results in bruising and laceration. A blow by a small instrument, acting locally, results in local rupture. Even in comparatively simple injuries, it is difficult to estimate the force of the blow. Who can measure the kick of a horse?

A hollow organ, if distended, is more vulnerable than if empty. Inquiry as to the previous meal time and as to the last micturition will afford valuable information. The exact direction of the violence is important; whether it is perpendicular, parallel or oblique to the anterior abdominal wall. The clothes of the patient should always be examined for they may offer some indication as to the injury.

The question to be immediately settled following an abdominal contusion is whether or not operative intervention is necessary. The evidence at hand will often be sufficient to justify, even if not to demand, an exploratory operation. On the contrary, the evidence may be insufficient for the making of an exact diagnosis. If an exact diagnosis is waited for, the favorable moment for a successful operation may be lost. The surgeon today is tempted to operate in an exploratory way upon slight provocation. Indiscriminate early exploratory operating for a diagnosis is to be deprecated. It is certainly better, however, to have operated many times and found no lesion than even once to have neglected operation when it might have saved a life.

Aside from the signs of lesions of individual viscera, already related in some detail, there are certain general conditions which may be present and which demand consideration in order to intelligently determine whether operation is wise or not. These are the conditions of shock, hemorrhage, and the extravasation of visceral contents causing peritonitis.

SHOCK; HEMORRHAGE; PERITONITIS.

The presence or absence of these three conditions will be determined by a proper interpretation of the pulse, temperature and respiration, by the existence and character of vomiting, nausea, pain, tenderness, rigidity and distension, by a knowledge of micturition and intestinal peristalsis, and last, but of utmost importance, by a true appreciation of the facies of the individual.

Shock. — Death has followed a blow upon the abdomen with no discoverable pathological lesions in the abdominal cavity. Death from pure shock! Almost every abdominal contusion of moment is associated with some degree of shock, whether a visceral lesion is present or not. Hemorrhage exists in many cases of abdominal contusion. Hemorrhage itself, even though not alarming, produces shock.

It is very important, and at times most difficult, to discover the etiological factors of the shock which is present in a given case. It is impossible to say positively that this much of the shock is dependent upon the blow alone, "nervous shock" so called, and that this much is due to hemorrhage, and this much is dependent upon the extravasation of the visceral contents. The differentiation of the causative elements of the initial shock necessitates keen discrimination in the interpretation of physical signs. The accomplishment of this differentiation will often solve the problem of operative interference.

Shock is very variable in individuals suffering from the same lesion. The temperament of the individual (seen, for instance, in the apprehension of a fatal issue), is often a factor in determining the degree of shock. The nationality of the individual influences materially the expressions of shock. These must all be taken into account. Shock will be manifested by a loss of consciousness. The unconsciousness may be more or less profound, dependent upon the degree of shock.

Pallor and perspiration of the face, low temperature, vomiting and nausea, chilliness and coldness of the extremities; a small, irregular compressible and rapid pulse beat; superficial respiration; anuria; less than the normal reaction to stimulation. These are evidences of shock. They all may be present, many may be absent.

A progressive improvement from the conditions of shock is valuable evidence that the patient may bear operative measures. Ordinary shock is recovered from within about three hours of the injury. Signs of reaction appear then and are soon well established. If recovery is somewhat delayed beyond this period there is presumptive evidence of a grave intra-abdominal lesion. Increasing shock after partial recovery from primary shock should suggest intra-abdominal hemorrhage or visceral rupture. Damaged tissues may be giving way. An absence of shock does not mean an absence of a serious lesion. Operation is absolutely contra-indicated in profound and continued shock.

Hemorrhage.—Bleeding inside the skull is harmful because of the irritation due to pressure. Hemorrhage within the abdomen is serious because of the loss in volume of the blood. In intra-abdominal hemorrhage the blood gravitates. Renal hemorrhage may be retroperitoneal. Dullness in the loin or loins, which changes to resonance as the patient is turned to the opposite side, is suggestive of free fluid blood within the abdomen, if other signs of hemorrhage be present.

In hemorrhage there may be shock, together with restlessness, thirst and a sighing respiration. Vomiting of blood may mean injury to the stomach or duodenum. Collapse with sudden exsanguination means rupture of a large vessel or extensive rupture of the liver or the spleen.

Reynier and Quenu have demonstrated that a slight rise of temperature is not incompatible with hemorrhage.

The *pulse*, of course, is variable. If there is shock the pulse will be rapid and feeble. It may be slow rather than rapid, if the depression is extreme. An increasing pulse rate with a low or subnormal temperature means hemorrhage, and demands immediate surgical interference.

The *temperature* is usually subnormal during the initial shock, particularly if the shock is considerable. The gradual rise of temperature to the normal point, associated with a falling pulse rate, denotes a favorable condition. A rise of temperature following an abdominal contusion usually means infection. The height of the rise in the temperature is not indicative of the severity or the extent of the infection.

Pain.— Shock diminishes the consciousness of pain. As the initial shock subsides, evidences of pain may appear. When pain is dependent upon hemorrhage, other signs of hemorrhage will be present. Pain of importance is evident in the face of the individual. The exact meaning of pain is often difficult to determine. Persistent local pain is important. In intestinal injuries it often locates the lesion.

Tenderness is usually general at first in an intra-abdominal lesion, but it soon becomes localized. Honest tenderness, that is, real tenderness, unbiased by the personal equation, coupled with pain, are the two most valuable signs pointing to the localization of intra-abdominal lesions.

Vomiting is very generally an early sign of shock. A simple emptying of the stomach once should not cause alarm. Constant and persistent vomiting means a visceral lesion. Unprovoked vomiting, a regurgitation, means peritonitis. Vomiting without other evidences of shock is significant, and vomiting which reappears after it has once ceased should cause concern.

Distension, with other signs of peritonitis, suggests serious infection.

Rigidity of the abdominal muscles indicates peritoneal involvement. Rigidity of the abdominal muscles and tenderness mean peritonitis. Pain, rigidity, tenderness together are unmistakable evidences of peritonitis.

It will thus be seen that the problem presented to the surgeon when he meets a case of contusion of the abdomen is definite in its demands, but often difficult of solution. These questions must be answered: Is operation necessary? Are there lesions of viscera? Two classes of cases should not be operated upon at first: (1) That class in which little or no shock is present; in which there are absolutely no localizing signs, and (2) that class in which profound shock, amounting perhaps to collapse, exists. Immediate operation is demanded in persistent moderate shock, with or without localizing signs. Immediate operation is demanded in cases of progressing hemorrhage. Immediate operation is demanded in cases of peritoneal infection. Having determined that definite lesions exist in any of the viscera, the form of treatment to be adopted is pretty generally accepted, and has been indicated under the consideration of each organ.

OBSERVATIONS ON THE USE OF ANTI-STREPTOCOCCUS SERUM IN THE TREATMENT OF PUERPERAL SEPSIS WITH A REPORT OF FIVE CASES.[1]

BY FRANK A. HIGGINS, M.D., BOSTON,

Assistant Visiting Physician for Diseases of Women to The Boston City Hospital; Physician to Out-Patients, Boston Lying-In Hospital, etc.

THIS paper has been prepared in the last few days as a consequence of your chairman asking me to report in a short paper my experience with the use of antistreptococcus serum in the treatment of puerperal sepsis. This paper is not, therefore, in any sense a review of the subject of puerperal septicemia, or even an expression of my views in regard to the treatment of the same, any more than may be pertinent in reporting the few cases in which the serum treatment has been employed, and in commenting on the results and treatment in these particular cases.

The antistreptococcus serum has now been in more or less general use for a number of years, and in this time has been subjected to a fair trial, by a large number of men and under varying conditions. In the aggregate, a considerable number of cases have been reported of its successful use; for the most part, however, they are reports of single isolated cases, and not reports of series of cases treated on a rational basis. Two years ago the committee of the American Gynecological Society collected over 350 cases in which the serum had been used, among which cases there was a mortality of 33%. This is believed to be higher than the average normal mortality in similar cases.

I believe that the general opinion of the profession at large, on the use of antistreptococcus serum in puerperal sepsis, is, that as a therapeutic measure it is a resource of very uncertain value, not to be relied upon with any certainty of success, and applicable only to a few cases as an accessory in desperate conditions.

My observations are confined to the use of the serum in 5 cases, all occurring in the past year, and these 5 cases I have reported in some detail. Before last year there were a few cases, but the notes of these were not available for hurried reference.

CASE I. C. H., thirty years. First seen in consultation May 15, 1900. On May 4th, patient delivered of a full-term child in absence of physician, and no examinations made either before or after delivery by the attending physician. She was sent to hospital and admitted with a temperature of 103.8°, pulse 120 and respiration of 40. Face flushed, dazed and apathetic at times, at other times wildly delirious. Fine tremor of hands and of tongue when protruded. Abdomen slightly distended and tympanitic, not tender and no spasm. Uterus enlarged, os patulous with considerable discharge. Intra-uterine douches and later curettage was performed without finding any débris of consequence. Urine, albumin trace with few hyaline casts. Patient was pretty sick for ten days, running a temperature from 100° to 103°, and her mental condition at this time was rather bad, depressed at times, at others very delirious; but at no time was her condition considered desperate or her life despaired of. Patient did well while in the hospital, but her recovery of strength and mental equilibrium was very slow, and she remained in the hospital nearly three months before she was ready for discharge.

This patient, before entrance, was given three injections of antistreptococcus serum, one daily, 20 cubic centimetres each time, and these injections were followed by daily remissions of temperature to about normal, the temperature going up again at night. After her admission to the hospital no more serum was administered, because her condition was not considered severe enough to demand it. It is possible that the serum may have influenced the case in its favorable termination, although I have always thought, as I did at the time, that the patient would have recovered without it. Her convalescence was slower than uncomplicated cases of puerperal sepsis, but not longer than septic puerperal manias usually require for recovery.

CASE II. E. F., twenty-five years. Entered hospital October 1, 1900. Italian. No history

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, January 23, 1901.

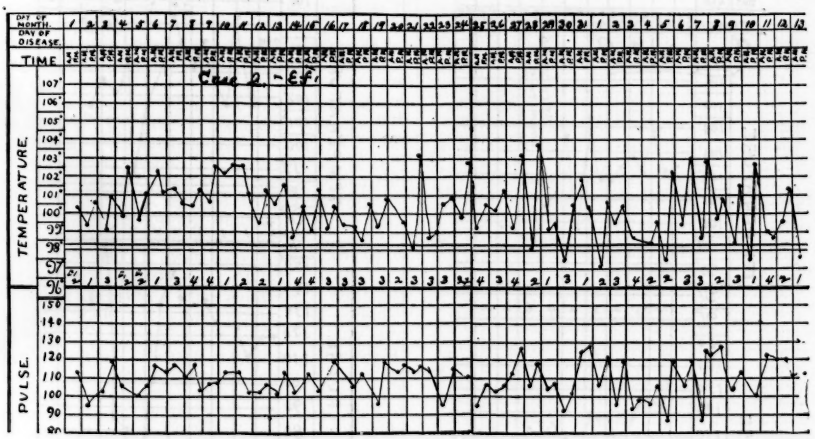
obtainable, except that patient was sent in for a septicemia and peritonitis after miscarriage. Patient in poor condition, weak, with high temperature and pulse; slight abdominal distention and tenderness; uterus enlarged and soft; os patulous with a considerable foul discharge. Patient was curetted shortly after entrance because of condition of uterus, and much foul material was removed. After curettage patient seemed to improve slightly for about a week, when the uterine discharge practically ceased. She was brighter, less apathetic and a little stronger apparently, although the temperature still remained high and very irregular.

After some days, the patient's condition not at that time improving perceptibly, she was given a bottle, 20 cubic centimetres of antistreptococcus serum. The injection did not have any noticeable influence on the patient's general condition or in her pulse and temperature; but she seemed to be holding her own after its use without any especial change, although being very weak.

Soon after the injection of the serum, a report on the products of the curettage was received from the pathologist, stating the condition to be tuberculosis of the uterus. This report rather nonplussed us at first, and it was with considerable skepticism that the report was received, as the case seemed clinically a typical puerperal septicemia, not only from the history, but also from the course of the disease and the uterine discharge. The patient was, therefore, kept under observation in the gynecological ward for nearly three weeks, and then, nothing new developing, she was seen by Dr. Sears, who agreed that the condition might be one of tuberculosis, and she was transferred to his service. At this time the abdomen was slightly distended, tender and tympanitic, and her condition generally resembling sepsis. She, however, died two weeks later.

Autopsy showed a general tubercular peritonitis while there were results of an extensive pelvic inflammation, the uterus being adherent to the bladder and drawn to the right and adherent to the right pelvic wall. The right tube and ovary were adherent to intestines, and the left tube to the pelvic wall.

This case was undoubtedly one of general peritoneal tuberculosis and tuberculosis of the uterus, with which occurred a puerperal infection of severe type. Because of these complications occurring together, it is scarcely fair to judge the action of the serum in this case by the patient's death, for had the existence of the tuberculosis been known before the serum was injected it would not have been used. It is probable that the woman was in very poor condition from the tubercular peritonitis, and the puerperal infection was merely the means of hastening her death.

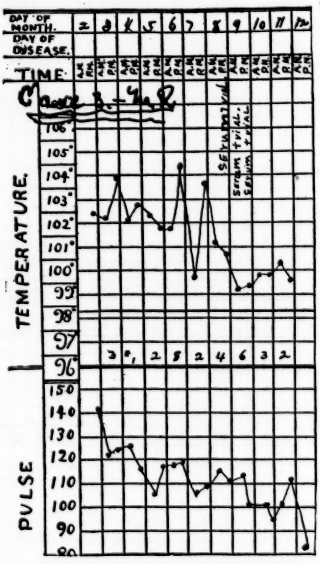


CASE III. M. R., twenty years. First seen October 2, 1900. Six days before, on September 26th, patient was delivered by forceps of a full-term child. Increasing pain, temperature and discomfort since delivery, when a consultation was held and she was removed to the hospital, having a temperature of 104.2° and pulse of 124. At entrance, pulse and temperature were elevated, eyes sunken, face anxious and there was mania present.

On examination, the abdomen was rigid and tender, not much distended. The uterus was enlarged, the os patulous, admitting the finger, and there was tenderness in both broad ligaments. The uterus seemed empty to the finger, although there was considerable discharge, and intra-uterine douches brought away some shreds. A curette was passed over the inner surface of the uterus, without ether, but nothing was obtained. The patient developed a pronounced mania, so that

constant restraint was necessary for her in the ward. The urine was normal in amount, containing a trace of albumin and a few hyaline and granular casts. The intra-uterine douches were continued twice daily. The patient failed gradually, in spite of all treatment, when on the sixth day she became entirely rational, no longer needing restraint, and remarked several times that she was glad to be again in her right mind.

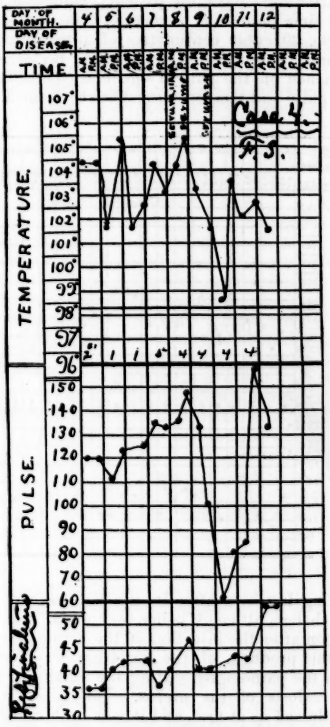
On this day, October 8th, 20 cubic centimetres of antistreptococcus serum was injected, 10 cubic centimetres in the morning and 10 cubic centimetres in the evening. The temperature chart is particularly interesting at this point, for while the regular chart shows a gradual decline from the first administration of the serum, yet the four-hour chart shows evening exacerbations on each day,



whether or not the serum was injected, varying between 103° and 104°.

On October 9th, the next day, there being no apparent improvement, 20 cubic centimetres of serum was injected in the morning and 20 cubic centimetres in the evening without any noticeable change. At this time, 60 cubic centimetres of serum had been given in all; there had been no change for the better in any respect. On the other hand, the patient had been growing steadily weaker and the pulse intermittent, so that the serum was discontinued, and the patient stimulated merely, until she died three days later, on October 12th, without any marked change having occurred in the symptoms.

The chart of this case is an interesting one, as I have already brought to your attention. The decline in the temperature and pulse following the injection of the serum, ordinarily favorable symptoms, without any amelioration of the patient's condition. I find we are very apt to look at a patient's chart, and, seeing a lower pulse and temperature, to at once conclude that there is improvement in the condition. I believe it is particularly true of septic conditions that the pulse and temperature chart is a poor guide in many cases, as the normal point is not infrequently reached only to react again shortly. I have also seen a patient die of sepsis in whom the temperature never rose above 100°.



CASE IV. F. S., thirty-seven years. Entered hospital on October 4, 1900. Six days before entrance, patient was delivered of a fetus of between four and five months for placenta previa. She was curetted soon after delivery for early sepsis. Patient was in a very poor condition and evidently profoundly septic. The uterus was enlarged, the os patulous, and the lochial discharge somewhat foul. The temperature was 104.2°, the pulse 118. There was dullness at the left base with marked bronchial breathing and numerous râles. Respiration at this time was not much

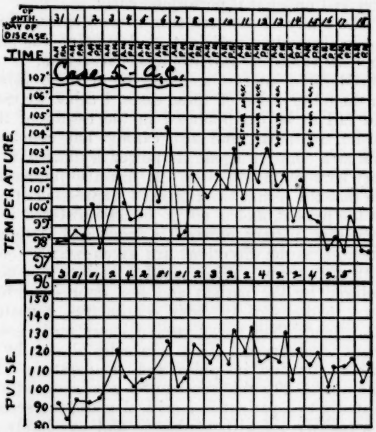
increased, but the next day it rose to 40, and patient unquestionably developed a septic pneumonia. The uterus was 5 inches in depth, the os admitting the finger, and a considerable amount of débris could be felt inside the uterus. The patient was therefore curetted, and the uterus washed out and packed with iodoform gauze.

The patient continued in a very serious condition, although for a few days she seemed to be improving slightly; but as this was only temporary, and her condition continuing very precarious, four days after entrance, on October 8th, 10 cubic centimetres of serum were given morning and evening without apparent result, and on the following day, October 9th, 20 cubic centimetres were given at one injection. Early the next day the patient's pulse and temperature fell rapidly to normal, and she almost collapsed, while the respiration remained unchanged at about 40 per minute. Under vigorous and free stimulation the patient rallied temporarily, while the pulse and temperature rose rapidly again to their former line. No more serum was administered, owing to its marked depressing effects. The patient died two days later.

This was a very critical case from the onset of the disease. The general septicemia was complicated by a septic pneumonia, which helped bring about the fatal result. No improvement of any sort was observed from the serum injection, 40 cubic centimetres being used altogether, while its use did result in marked depression of the vital forces, bordering on collapse.

Case V. A. C., twenty-six years. Admitted to hospital on December 31, 1900, for pelvic abscess and septicemia after childbirth. Confined by midwife 40 days before entrance, and operated for vaginal puncture a few days before being sent to the hospital. Patient was poorly developed and nourished, and her general condition was very seedy. Chest negative, except for a soft systolic murmur at apex. Pulse poor and feeble, 92 per minute, temperature 98°. Abdomen rigid with considerable tenderness, which prevented any satisfactory examination, except that there could be felt a mass in abdomen of considerable size extending half way to the umbilicus. Urine contained trace of albumin, much pus, and numerous hyaline and granular casts and a few brown granular casts. Just to the left and posterior to the cervix was a small opening in the vagina, extending into a cavity into which was inserted a small iodoform wick with not much discharge. This wick was removed daily, the cavity irrigated through a small tube with normal salt solution, and a new wick inserted, while the patient, being in a very poor general condition, was nourished and stimulated. This treatment was continued until the seventh day, when her evening temperature reached 104.4°, having before this maintained a general tendency upwards, as may be seen by a study of the chart. As there was little discharge from the cavity through the vaginal sinus at this time, it seemed probable from the continued rise in temperature that there was an accumulation of pus in the pelvis which was dammed up and not finding a ready exit. Therefore, it seemed best to give the patient a little ether, which was done, and an incision made posterior to the uterus transversely about one inch long from the side of the old opening through the vaginal wall. Through this opening, with my finger, I carefully separated the tissue up into the cavity which had previously been punctured and was being drained by the wick. No accumulation of pus was found there or elsewhere in the pelvis. The uterus was large, firm and anterior. The cavity was irrigated with salt solution and packed with iodoform gauze, the whole operation not lasting longer than ten minutes at the outside, and very little ether being used.

After the vaginal section the temperature ranged between 101° and 102° for three or four days. There was no marked change in the patient's condition, except it was evident there was no improvement, while on the whole the pulse was averaging a little higher, being about 120 per minute, and there seemed to be some loss of strength.



Other measures having failed, I thought it would be at least worth while to give the serum treatment a trial; accordingly, on the fourth day, 20 cubic centimetres of antistreptococcus serum was injected. This injection was repeated on the fifth, the sixth and the eighth days, when there was a marked decline in the temperature, and the patient seemed brighter and better, although still very weak. No more serum was injected, 80 cubic centimetres having been used in all. The temperature was subnormal on the ninth day, being 97.6°; but, nevertheless, the patient appeared to gain a little during the next few days, and seemed to be making fair progress on the road to recovery, when she suddenly collapsed and died in the morning, four days after the last serum was administered, twelve days after the operation, and about sixty days after delivery.

This case illustrates fully the disadvantages under which many of these cases are received into the hospital and treated there, entering in a very weak condition after a period of prolonged septicemia, already continued nearly six weeks, with probably only the most meagre care and surroundings through it all.

It seems fair to assume, and I am willing to admit, that the second operation which I performed was in a measure detrimental to the patient's interests, as it resulted in no improvement, and the probable conditions were not found as expected. On the other hand, the condition was gone over very carefully, and without relief in some form she seemed to be rapidly approaching a fatal termination.

I have never seen but one case up to the present time in which I have felt that hysterectomy was justified for puerperal sepsis, but possibly this case which I have just recounted might have survived under it if performed early.

The study of the results in these 5 cases, while not in themselves sufficient to determine the permanent value of antistreptococcus serum, is of considerable interest and may be of some value. In the observation of these cases, I think we cannot fail to be disappointed in the results of the serum treatment, and also cannot but conclude that as a curative agent its power is limited to a very narrow line of cases. It has also impressed me that the serum has a marked depressing effect on the patient, and is not to be administered to a very sick patient offhand in large and frequent amounts, as the directions are given which come with the serum. When used, I believe it is best endured by the patient and less depression follows, in doses of 10 cubic centimetres, repeated not oftener than every twelve hours until some result is observed. This is usually shown by a marked decline in pulse and temperature. In amounts of 20 cubic centimetres administered repeatedly to a patient in a critical state, the serum is a remedy not without danger and one likely to result in dangerous symptoms.

It is important to bear in mind that these cases of mine were all extremely sick, and in very critical, if not desperate, condition at the time the serum treatment was begun. But none of these cases were moribund, or even so critically ill that it was not considered at least that there was a good fighting chance. It is certainly in these cases that we should expect the serum to assist, if at all, as the milder cases recover without its use.

The mortality of puerperal sepsis, of all cases, mild and severe, is usually believed to be about 25%. In the City Hospital, where we see every year a large number of cases of this class, it certainly is not greater than this, and my impression is that it is somewhat lower. On this subject I hope to present a paper at a later date. In some cases much importance has been attached to the fall of the pulse and temperature which often follows the injection of the antistreptococcus serum. This fall in pulse and temperature does seem to be an atttendant symptom on the injection of the serum, but that is not always an entirely favorable symptom and is not unattended by danger. I am convinced that it is rather a signal of danger and an indication of impending collapse. This occurred in 2 of my cases, only shortly before death, and in one of these the pulse and temperature rose immediately, after touching normal, to 160° and 103.6° respectively. Moreover, severe cases of puerperal sepsis treated, without the use of serum, have frequently in the course of the disease remissions of pulse and temperature, only to recur again in a day or two when one is just ready to conclude that the disease has about run its course.

In every case of puerperal septicemia the virulence of each particular infection, the extent of the constitutional infection and the ability of the individual patient to combat the trouble, all have a direct bearing on the severity of the disease and on the ultimate result.

In puerperal sepsis the streptococcus is generally recognized as the main etiological factor, while a few other varieties of bacteria, as the staphylococcus and the colon bacillus, are believed to be the cause in certain cases, and in others the so-called mixed infections, when two or more of these bacteria are believed to be the exciting causes. In a few cases of pure streptococcus infections the antistreptococcus serum is apparently of great value as a life-saving measure. The varieties of the streptococcus are so many that it is only an occasional case that will be helped by the serum treatment. While in the majority of cases of streptococcus infection, and in all cases of mixed infections, it is useless to expect the serum to cure the disease.

I believe that the serum treatment has no place in the routine treatment of puerperal sepsis, that it should be used only in desperate cases after failure to obtain improvement by other and usually more efficient methods, and that if no improvement is shown after use for two or at most three days and the injection of 40 cubic centimetres to 60 cubic centimetres, it should be discontinued. I believe that its use is not free from danger, that it usually lowers the pulse and temperature, but at the same time it has a correspondingly depressing effect upon the patient, and that it has not apparently lowered the mortality of the disease.

With regard to the general treatment of puerperal sepsis, early curettage of the uterus carefully performed as soon as the diagnosis is established is, I believe, of primary importance, and the same result is not accomplished in my opinion by any other method of procedure. If carefully done it can result in no harm, and if efficiently performed it always removes the primary focus of the disease, and not infrequently removes the disease at its outer limits.

Following curettage, and sometimes in place of it in the mild cases, intra-uterine douches have proved to be of much value.

For constitutional treatment we must mainly rely on stimulation, tonics and forced feeding, with moderate diuresis and catharsis.

A CASE OF CÆSAREAN SECTION IN A FACE PRESENTATION, COMPLICATED BY UTERINE FIBROID.[1]

BY EMMA S. CALL, M.D., BOSTON.

On the evening of November 13, 1900, I was called by one of the internes of the Pope Dispensary, to a case of face presentation. I arrived about 10 P.M. and found Mrs. B., a healthy-looking Italian woman, age twenty, in labor with her second child. Her first labor, fifteen months before, was apparently normal and not unusually long. Her pelvic measurements were said to be normal. Labor pains began about noon of November 4th, but were not sufficiently severe to induce her to call a doctor till 7 P.M.

Upon examination, the os was found dilated about the size of a dollar, the membranes present but relaxed, and the face presenting in the right mentoposterior position, but above the pelvic brim. This position of the face is, I believe, held by the best authorities to be an indication for interference, owing to the impossibility of delivery, if rotation forward fails to take place in the pelvic cavity. I therefore decided, as soon as the os was sufficiently dilated to permit the easy introduction of the hand, to try first to change the presentation into one of the vertex, or, if that failed, to perform version.

About midnight, the os being fairly well dilated, ether was given, and the attempt was made to flex the head. This was unsuccessful, and after considerable time abandoned. The hand was then introduced into the uterus, the membranes ruptured, a foot seized and brought to the os, but the combined efforts of my hand internally and those of my assistants externally failed to push the head sufficiently from the pelvic inlet to allow the revolution of the body necessary to complete the version. This immobility was not because of any impaction of the head, which was still above the pelvic brim. The whole lower segment of the anterior wall of the uterus seemed thick and unyielding, and the difficulty was increased by the very small amount of liquor amnii.

After a considerable time spent in ineffectual attempts to complete the version, I sent for further assistance, and Dr. Alexander kindly responded. Although the patient had been kept under anesthesia, the manipulations had excited quite vigorous uterine contractions, and when Dr. Alexander arrived, it was considered by both of us unsafe to make any farther attempts at version. These contractions, however, seemed to have no effect in pushing the presenting part downward.

The life of the child was now seriously jeopardized, if not extinct, and we therefore felt that the interest of the mother must be the sole consideration. To try and extract by high forceps seemed useless and harmful, nevertheless the forceps were applied and an endeavor made to compel the face to enter the pelvis, where, if rotation failed, craniotomy could be more easily performed; but a short trial showed that the presenting part could not be dragged down without force, which would be very serious to the mother's soft parts.

The patient had now been under ether over two hours, and began to show signs of exhaustion, and it was evident that something must be done to deliver her quickly. The choice lay between craniotomy and abdominal section. Craniotomy on the face above the pelvic brim, with extraction, seemed to us both to be a more serious operation than section, though we realized that the manipulation to which the uterus had been subjected, was a decided drawback to the success of the operation.

The question of removing the patient to the hospital was considered; but it was felt that the delay necessarily involved in getting her there, would be more dangerous than to do it at once at home. Fortunately, it was one of the better class of tenements, and unusually clean.

The operation was performed by Dr. Alexander, who has kindly permitted me to report the case, although the honor of its successful termination belongs to her.

An abdominal examination now showed a distinct prominence, involving the left side of the uterus from the pubes half way to the umbilicus, and extending laterally about 7 cubic centimetres to the right of the median line. This surface was very hard and unyielding, and stood out quite plainly during the uterine contractions. On account of this, the uterine incision was made a little to the right of the median line, and only passed through a small part of this prominence.

The child was quickly extracted, and it was then seen that this appearance was caused by an interstitial fibroid, the part through which the incision passed being about 7 cubic centimetres in thickness. The uterus was sutured with silk, and the abdominal walls with silkworm gut. The patient was returned to bed in fairly good condition, the uterine contraction being very satisfactory.

The after history of this case was a very gratifying one. There was some distension on the second day, which was relieved by free action of the bowels and never returned. The wound healed by first intention, and the convalescence was quite uninterrupted.

I examined her about two weeks ago, eight weeks after delivery. The uterus was very little larger than normal, was perfectly moveable, and only a moderate thickening induration of the anterior wall remained.

This satisfactory result was largely due to the careful and constant aftercare given to the patient by our dispensary internes, Drs. Harrington, Myrick and Farquarson, and the dispensary nurse, who devoted themselves to her so assiduously that she was not left alone day nor night during the first week. Later we were much indebted to Miss Strong, director of the class for invalid attendants, who allowed some of her pupils to assist us.

In reviewing this case, our regret is, of course, that we did not operate earlier, when we could

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, January 23, 1901.

undoubtedly have saved both mother and child. The fact that the woman was only twenty years of age, that she had borne a child without difficulty within two years, and that the tumor, being interstitial, was not so prominent as to make its nature and extent realized until powerful uterine contractions had set in, are some of the facts which led to this mistake.

Clinical Department.

NOTES FROM THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

EXOPHTHALMIC GOITRE AND FRIGHT.

BY E. W. TAYLOR, M.D., BOSTON.

THE etiological relationship of various neuroses and fright has long been recognized, however difficult of explanation the association may be. A peculiar interest attaches to exophthalmic goitre in this connection, because of the fact that in its characteristic form it so perfectly represents the physiological appearances associated with fear. One's experience, however, by no means invariably bears out the supposition that fear is always the exciting cause of the neurosis; in fact, a sufficiently definite association of fear and subsequent symptoms to be of any scientific value is relatively unusual.

The following cases are reported as a contribution to the general subject. All 3 came under observation within a period of five weeks, 2 at the Massachusetts General Hospital and 1 privately. In each, careful inquiry disclosed no other adequate cause for the development of the disease than fright. All were in women.

CASE I. L. H., a housekeeper by occupation, of Irish birth, twenty-eight years of age, had been perfectly well up to October, 1900. Her appearance, when seen at the hospital, justified her claim to health and general nervous stability. In October she was violently frightened by being suddenly roused from sleep, and seeing a man looking in through the window, her sleeping room being on the ground floor. She was for a time wholly overcome by fear, was unable to move, and had a sensation of extreme weakness, which she described as "collapse." Typical nervous symptoms at once appeared, associated with a dread, not yet wholly overcome, of going to a window. She continued to feel unnerved and unlike her former self. She did not, however, notice the presence of a goitre. Several months later, the foregoing symptoms persisting, she was again violently frightened in a similar manner. Soon after this, she noticed an enlargement of the neck, with accompanying nervous symptoms of a marked sort. She is perfectly confident the goitre did not exist before, a matter about which it is entirely unlikely she could be in error, especially since she in no way associated the thyroid enlargement with what had gone before.

Physical examination, March 11th, showed a well marked goitre, not completely bilateral, no exophthalmus, a somewhat irregular pulse of 102, and a certain amount, though not excessive, general nervousness. The heart was normal; the knee jerks within normal limits, and the mental state not noteworthy. The patient presented the picture of an extremely mild, though undoubted exophthalmic goitre.

Improvement has been continuous since first seen, and although the goitre persists there can be no doubt that, under proper care and treatment, the condition will wholly subside.

CASE II. N. H., married woman of thirty-three, of American birth. Twelve years ago, while not in the best condition, the patient witnessed what she thought to be the drowning of her brother. She had immediately fainted on seeing the boat capsize in which her brother was, and on recovering consciousness still thought him dead, which naturally added to her fright. Immediately thereafter symptoms of marked general nervousness, with sensations of weakness, came on, which she is confident she had not had before. Two months later exophthalmus appeared, soon followed by bilateral goitre. For nine years she has been annoyed with rapid heart beat.

Physical examination now shows a perfectly typical picture of exophthalmic goitre; extreme exophthalmus, with slight Græfe's sign; goitre of moderate size, unequally bilateral; pulse 138, regular; typical fine tremor. The condition has remained practically unchanged for several years, under more or less intermittent treatment. The patient has not herself associated her disease with the fright she received at the time of her brother's accident.

CASE III. E. G., a student nurse, unmarried; twenty-eight years old; a native of Canada. She had been unusually conscientious in her work, but had been well up to the latter part of last year. In November, while nursing outside of the hospital, largely on her own responsibility, on one occasion she came into the room in which her patient was, and found her lying on the bed unconscious, and, as she thought, dead. Investigation showed that she had merely fainted as a result of some unusual physical exertion during the absence of the nurse. On recalling this occurrence, the patient distinctly remembers the violent fright into which she was thrown, though here again she did not herself associate the fright with her subsequent symptoms. She went on with her work, and a few weeks later, in December, had another difficult case, resulting in the death of the patient. Symptoms of general nervousness came on, tremor, poor appetite, and difficulty in doing her work. Seen a little later she presented unequivocal signs of exophthalmic goitre: loud, somewhat irregular heart beat; pulse 140; considerable exophthalmus; evident but not large goitre; general tremor; and much appearance of nervousness.

In each of these cases the association of a definite violent emotional disturbance, with the symptoms which came on immediately subsequently, is

too close to be disregarded. The fact of mere coincidence is, of course, never to be dogmatically denied, but it is certainly no straining of a point to maintain the decided probability of cause and effect. Some unknown predisposition, as in all other diseases, must be assumed; but the exciting cause, reasonably enough, may be regarded as the fright. No doubt a more careful investigation than is often made, of the immediate antecedents of the neurosis, would show an emotional disturbance as its precursor in a considerable number of cases. The manner of development of this perfectly characteristic disorder from such a cause is naturally, as yet, quite beyond our power of comprehension. If clinical experience bears out the etiological relationship it must none the less be accepted and seriously regarded, even though our knowledge as yet be purely empirical. The important part is the recognition of the possibility of the deleterious effects on the nervous system of physical traumata. There has been dispute enough about the matter in its practical bearings with relation to the recovery of damages in accident cases. One recalls a somewhat recent ruling denying damages to a plaintiff who has not received a physical injury. However practically useful such a general decision may be from a legal standpoint, in dealing with accident cases, it clearly has no medical justification. Every one who has followed the subject, is aware that in very many cases the original physical injury plays a small part in the ultimately developed neurosis. The physical effect in these disorders is by far the most important element to be considered. If courts can rule that physical contact is essential to establish a case, they must also rule that a neurosis like exophthalmic goitre, about the identity and reality of which there is, and can be, no question, should not be admitted to litigation if its apparent cause is attributable only to violent emotion. From every point of view it is desirable that cases should be reported to the end that more light may be thrown upon a problem, which is of the most intimate concern, not only to the physician, but to the public at large.

Medical Progress.

REPORT ON PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

REPORT OF THE COMMITTEE OF THE AMERICAN SURGICAL ASSOCIATION ON THE MEDICO-LEGAL RELATIONS OF THE X-RAYS.

DR. J. WILLIAM WHITE presented a report on the medico-legal relations of the x-rays at a meeting of the American Surgical Association in May, 1900,[1] and offered the following conclusions:

(1) The routine employment of the x-ray in cases of fracture is not at present of sufficient definite advantage to justify the teaching that it should be used in every case. If the surgeon is in doubt as to his diagnosis, he should make use of this as of every other available means to add to his knowledge of the case, but even then he should not forget the grave possibilities of misinterpretation. There is evidence that in competent hands plates may be made that will fail to reveal the presence of existing fractures or will appear to show a fracture that does not exist.

(2) In the regions of the base of the skull, the spine, the pelvis and the hip, the x-ray results have not as yet been thoroughly satisfactory, although good skiagraphs have been made of lesions in the last three localities. On account of the rarity of such skiagraphs of these parts, special caution should be observed when they are procured in basing upon x-ray testimony any important diagnosis or line of treatment.

(3) As to questions of deformity, skiagraphs alone, without expert surgical interpretation, are generally useless and frequently misleading. The appearance of deformity may be produced in any normal bone, and existing deformity may be grossly exaggerated.

(4) It is not possible to distinguish after recent fractures between cases in which perfectly satisfactory callus has formed, and cases which will go on to non-union. Neither can fibrous union be distinguished from union by callus in which lime salts have not yet been deposited. There is abundant evidence to show that the use of the x-ray in these cases should be regarded as merely the adjunct to other surgical methods, and that its testimony is especially fallible.

(5) The evidence as to x-ray burns seems to show that in the majority of cases they are easily and certainly preventable. The essential cause is still a matter of dispute. It seems not unlikely, when the strange susceptibilities due to idiosyncrasy are remembered, that in a small number of cases it may make a given individual especially liable to this form of injury.

(6) In the recognition of foreign bodies, the skiagraph is of the very greatest value; in their localization it has occasionally failed. The mistakes recorded in the former case should easily have been avoided; in the latter they are becoming less and less frequent, and by the employment of accurate mathematical methods, can probably in time be eliminated. In the meanwhile, however, the surgeon who bases an important operation on the localization of a foreign body buried in the tissues, should remember the possibility of error that still exists.

(7) It has not seemed worth while to attempt a review of the situation from a strictly legal standpoint. It would vary in different States and with different judges to interpret the law. The evidence shows, however, that in many places and under many differing circumstances the skiagraph will undoubtedly be a factor in medico-legal cases.

(8) The technicalities of its production, the manipulation of the apparatus, etc., are already in the hands of specialists, and with that subject, also, it has not seemed worth while to deal. But it is earnestly recommended that the surgeon

[1] American Journal of the Medical Sciences, July, 1900.

should so familiarize himself with the appearance of skiagraphs, with their distortions, with the relative value of their shadows and outlines, as to be himself the judge of their teachings, and not depend upon the interpretation of others who may lack the wide experience with surgical injury and disease necessary for the correct reading of these pictures.

RESEARCHES ON THE ASSUMED CONTAGIOUSNESS OF ERYSIPELAS.

Dr. Wilhelm Respinger[2] treats on this subject as follows:

The well-grounded teaching of the contagiousness of erysipelas is based on the epidemics prevalent in pre-antiseptic days as well as on its diminution, save in sporadic form, since the antiseptic era, and finally, on its prevalence alongside of certain specific wound infections; for example, puerperal fever and cellulitis, which have turned out to owe their origin to a common micro-organism. This micro-organism has subsequently been found in rooms occupied by erysipelas patients.

Just how the contagium is disseminated has not been proven. In cases where the erysipelas followed in the wake of an open infected wound, direct infection is evident, and its spread to others under such circumstances is dependent on the contamination of dressings and utensils; wherefore the finding of cocci in such quarters tenanted by erysipelas patients has rightly been attributed to a possible dessication and dissemination of the germs from dressings and the bedding.

In view of the fact that a large number of cases of erysipelas exist without a wound, just how these are responsible for propagating the contagium, when it is recalled that the process is a lymphangitis, at first sight appears mysterious. The author has, therefore, sought to prove by experiment that the contagion was spread by the dissemination of atomized particles of the scales which result from the desquamation or from the atomization of the contents of vesicles. Von Eiselberg found this to be the case. Against this the author contends that his cases were accessory to wound infections. To eliminate such infection of scales by continuity, the author chose only idiopathic cases, and in no instance did he succeed in gaining streptococci from the scales; whence he concludes that these, being the only channels by which the contagium can in any atomized form leave the intact skin affected with erysipelas, the latter cannot be classed, *strictu sensu*, as contagious.

The contagium streptococcus always gains its entrance by a wound, however small. At this site the virus is particularly virulent, and its contagiousness is to be viewed only in the same light as any other wound infection. Thus, with erysipelas placed in the same category as streptococcus abcesses and cellulities, the latter, with their exposed surfaces, are infinitely greater purveyors to the spread of this infection than an ordinary facial erysipelas. Treatment should none the less be carried on under the strictest antiseptic precautions; but in this light there ought to be as much obligation to report a streptococcus abscess as an erysipelas to the health authorities.[3]

CARBOLIC GANGRENE.

Dr. Francis B. Harrington read a paper on the subject of carbolic gangrene at a meeting of the Massachusetts Medical Society, June 12, 1900,[4] from which the following extract is made:

That dilute solutions of carbolic acid, applied to the extremities for a number of hours, may produce gangrene and total destruction of the part, is a fact of which the public at large and even many physicians are ignorant. It is an unfortunate result of the popularization of the antiseptic treatment of wounds. Carbolic acid, once the favorite antiseptic among surgeons, and now discarded, has become a general household remedy for the treatment of slight wounds and bruises. During the last five years at the Massachusetts General Hospital, I have discovered myself, or have seen through the courtesy of the out-patient surgeons, 18 cases of gangrene from this cause. In a large proportion of these cases, amputation has been necessary. These, together with cases which I can find in the medical literature of various countries, make a total of 132 cases of gangrene from dilute solutions of carbolic acid. It would be safe to assume that many hundreds of fingers have been destroyed from this cause. Doubtless many cases occur and are not recognized as due to carbolic acid, and these with many others are never reported. Usually the patient has come to the hospital with a story of having treated a cut, a bruise or a felon with a solution of carbolic acid which has been purchased from an apothecary for the purpose. Occasionally the treatment has been suggested by a physician.

The facts are these: An aqueous solution of carbolic acid (1% to 5%), if applied to an extremity, as the fingers or toes, for a number of hours, in the form of a moist dressing or poultice, may produce gangrene and total destruction of the part. This result is not from compression, but simply from the action of the carbolic acid.

It has been asked why gangrene does not appear on the trunk. Superficial gangrene does occur if the application is sufficiently prolonged and the saturation of dressings is great enough. The result is not so disastrous because of the greater thickness of tissues and because the blood supply cannot be shut off as it is in an extremity. It is the enveloping of the entire part, as the finger or toe, with the dressing which causes the complete destruction of the part, since the gangrene only affects those parts which are thus covered.

The public must be taught to use some safer treatment. Moist dressings are often very soothing and helpful in slight injuries of the fingers or toes. A large part of the benefit to be derived from any form of moist dressing can be obtained

[3] Beitr. zur klin. Chir., Bd. xxvi, H. 2.

[4] American Journal of the Medical Sciences, July, 1900.

by using boiled water on clean compresses. Safe household remedies for this purpose are tincture of hamamelis or solutions of borax or boric acid.

It is evident that carbolic acid solutions in any strength applied as a moist dressing are dangerous and ought never to be used. The fact that it is often used without bad results renders it the more dangerous. It is the duty of the medical profession to see that this needless destruction of fingers is stopped. Carbolic acid in any strength should be included in the list of those drugs which can only be procured by a physician's prescription. Whatever the strength, it should always be labeled as dangerous.

(To be continued.)

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

W. H. GRANT, M.D., SECRETARY.

Regular meeting Wednesday, January 23, 1901.

Dr. E. S. Boland, the chairman, opened the meeting with the following remarks:

While our change of meeting place may make no special difference to our section, still it seems hardly civil to omit extending our hearty congratulations to the Medical Library, whose guests we are, on the opening of their beautiful home. Incidentally, we may felicitate ourselves on such pleasant quarters as are furnished here for us by the parent society at no added expense to us as a section.

As a member of the Library, and by your courtesy chairman of this section, it gives me great pleasure to welcome you here tonight. Ten days ago this building was dedicated to its use as a library with the expressed hope that, as a professional meeting place, added usefulness might ensue. At that dedication Professor Osler spoke of the value to the members of the "Attrition of the Medical Society." For the benefit of any who did not hear this man of clearest insight, let me quote three sentences of incisive truth which ought to be memorized by every one of us. "For the general practitioner, a well used library is one of the few correctives of the premature senility which is apt to overtake him. Self-centred, self-taught, he leads a solitary life, and unless his daily experience is controlled by careful reading or by the attrition of a medical society, it soon ceases to be of the slightest value, and becomes a mere accretion of isolated facts without correlation. It is astonishing with how little reading a doctor can practice medicine; but it is *not* astonishing how badly he may do it."

I suppose that we all, in theory, at least, recognize the need of up-to-date literature and professional intercourse; but as we get older we let the little cares and nearer duties crowd out these larger interests that go to make up the possibilities of our lives. It is so everywhere. It was stated in a periodical the other day that, out of a membership of over 500 the London Practitioners' Society had, at the meeting in question less than 15 were present. The "solitary life" which we are prone to lead is our weak point professionally as compared with the law. There, constant professional contact in antagonistic action eliminates the inefficient and develops the strong in their ranks. After graduation and hospital training, except for an occasional consultation, we are not of necessity brought together either in friendly or contentious association, and for professional growth the conditions are not good, but this is the lot of most of us. The fortunate few, on hospital staffs or in teaching positions, get the "attrition" that we need so much and get so little of in our daily work. Strangely enough, we fail to grasp our needs, and the men who are usually found at the meetings are not always the ones who need the benefits the most.

To go back to the Library, there is one feature of the case that ought to appeal to us: — With the passing of the preceptor and student relation — in which passing each has lost much — the practitioner not connected with school or hospital is doing nothing for the profession to which he owes so much. It is little enough, then, that he should contribute to the maintenance of the Library where medical students are welcomed and helped, and where the men in the profession who have the time and taste for study get the results which help us all directly or indirectly in the end. To escape "premature senility" then, our best hope would be to attend the sections which appeal to us most, as a duty which we owe ourselves individually; also to join the Medical Library even if not readers ourselves, and so repay to some extent our obligations to the profession.

Dr. H. O. Marcy read a paper entitled

GYNECOLOGY: ITS CONTRIBUTION TO GENERAL SURGERY.

Dr. Boland: I think it is very hard for any one who has been through the school since the day of aseptic surgery to realize what it was before that; the carelessness with which operations were done. I feel loath to let such a subject go by without discussion. The thought occurred to me how much we owe to gynecology in the domain of obstetrics. I am sure obstetricians will admit that they have received immense advantages over the treatment of twenty-five years ago in the demonstration of the possibilities of gynecology.

Dr. Emma L. Call reported

A CASE OF CÆSAREAN SECTION IN A FACE PRESENTATION, COMPLICATED BY UTERINE FIBROID.[1]

Dr. Higgins: I do not know that I can add anything of value. I think that recovery from the operation of Cæsarean section, done in a tenement house under these circumstances after the patient has been in labor for a long time, is certainly a cause for congratulation. It strikes me

[1] See page 427 of the Journal.

as being a very unusual case of face presentation with the head high at the brim in which the head could not be flexed or rotated. I have known of a recent case of face presentation in the pelvis posterior where the head could not be flexed, but where it was pushed back and version done. I should think that ordinarily we would consider that an impacted head as this seems to have been indicates craniotomy rather than Cæsarean section at this time.

DR. E. W. CUSHING: I think the case reflects great credit on those who carried it through so successfully. It occurs to me that all these cases, when reported, are of the greatest value in leading the minds of the profession to consider Cæsarean section earlier, as being in these times a comparatively safe operation which can be done, as it is really, with the saving of the life of the child and with fully as little risk to the mother, very often, as a severe case of obstetrics, terminated with great difficulty by the forceps, or even by craniotomy. For you are not quite safe in craniotomy from injuring the mother, and certainly the life of the child is worth a good deal. I would like to ask the doctor if this incision went right through the fibroid? If so, whether it would be possible to have enucleated it, or if the fibroid was large enough to cause the question of removing the uterus to be considered? I did not understand how large the fibroid was. It may be the fibroid was so large it would be a favorable time to remove the uterus, although I can imagine that in such a vascular affair as the pregnant uterus it would not be a favorable time to enucleate the tumor. The cases of fibroids complicating pregnancy are not so very uncommon. I have had three or four where it was necessary to remove the uterus for a fibroid where pregnancy was present as a complication. One such case was in the wife of a physician a few months ago. There was a large fibroid in the lower part of the uterus, so that delivery would have been impossible. She was pregnant about three months. I have had, I think, 4 cases of that kind, although not at term. I have seen Dr. Price, of Philadelphia, remove the pregnant uterus, fibroid and child by Porro's operation, twice, I think. So far as I know all these have done well, so that my opinion would be in favor of a Cæsarean section in competent hands as against craniotomy where the child is living.

DR. ALEXANDER: In reply to Dr. Cushing's inquiry concerning the enucleation of the fibroid, that was thought of at the time, but it was decidedly interstitial and occupied the entire thickness of the uterine wall from the mucosa to the peritoneum, so that it was not possible to have enucleated under any circumstances, whether it were pregnant uterus or otherwise, and there was no doubt in our minds at the time as to the route, that delivery must be effected abdominally; but there was a question after the child had been delivered as to the best method of finishing the operation, whether to do a conservative Cæsarean or a Porro. The woman was very young, about twenty, very anxious to have more children; all the manipulations as far as the preceding ones were concerned had been done carefully, and under proper precautions, so that the uterus was probably not septic, and the fibroid could not be enucleated. It was, therefore, decided to do a simple conservative Cæsarean, and the result seemed to justify the conclusion.

DR. GOLDTHWAIT: I might mention 1 case which occurred about twenty years ago. I attended a colored woman in confinement, and it was impossible to deliver by the natural passage. I called Dr. Aikin in, who found the case rather beyond his powers, and he called Dr. Storer. Each one of us tried to deliver with forceps. Failing in this, craniotomy was resorted to. The operation was done with great difficulty. The child was very large, the pelvis somewhat deformed and contracted. There was also in the wall of the uterus a fibroid, apparently like the one mentioned. It had nothing to do with the failure to deliver, however. She recovered, and several months later came to me with a great deal of pain and considerable enlargement of the womb. I could not determine whether it was this fibroid or not. She had not had her periods since the operation. I called in a young confrere at that time to see her with me. We could not make out what the trouble was. It was impossible to find a well-defined os. A month later she returned complaining of a great deal of pain. We again examined with a like result. The next day, however, she came to my office, and after a very protracted examination, I thought I felt what should be the os. I succeeded in introducing a blunt sound. On its withdrawal, I should think a pint of blood followed. Apparently it had been confined there. I suppose the os had become occluded by the instrumental manipulations, and a fragment of bone. I do not know that I ever heard of anything like that. She recovered and became regular, though never again pregnant.

If, at the present day, I were again confronted with similar conditions I should resort to Cæsarean section, thereby giving the child a chance for life without increased risk to the mother.

DR. HIGGINS: In my remarks I did not intend to criticise the operator, nor would I wish to be considered as advocating craniotomy on a child who had a fair chance of being saved by Cæsarean section, and certainly never would advise it or do it on a living child if the mother were in good condition; but it seems to me a case of impacted head high, which could not be pushed back to flex or rotate or do version, would be considered as an impacted head, and probably an impacted head under those conditions could not be removed without great difficulty and considerable strain on the child even after opening the abdomen. Symphyseotomy would undoubtedly release the head under such conditions, and would in my opinion be a conservative operation to perform if the child were alive, and if not I should not hesitate to advise craniotomy. It would seem to me to be a very unusual case in which Cæsarean section would be indicated, or would be considered a conserva-

tive operation if the baby were not living. I am sorry Dr. Call did not say more about the condition of the baby, whether the baby's heart was beating before and also after delivery. These conditions are important, I think, in guiding us to future operations.

DR. CALL: The baby's heart was beating until within a short time of the Cæsarean section, but we were not sure of it at the time we began the operation. I know it seems as if there were a very decided want of skill to say that the head could neither be flexed, nor version performed. Of course no one can tell whether some one else could not have done it. All I can say is, that this fibroid was more like an infiltration than a distinct tumor, and seemed to involve a great portion of the anterior wall of the uterus on the left side and extended into the right, so that the whole lower segment appeared to be unyielding, and, moreover, I do not think there was more than a cupful of liquor amnii. The membranes were not ruptured, until I had tried for some time to flex the head. I think those two conditions were undoubtedly the cause of our failure to do the usual operation, and, in fact, the reason I suppose that the abdominal operation was delayed so long, was because it seemed to me as if it must be done, and I think I worked over it longer than I should have done. The whole of the presenting part was above the pelvic brim, and the anterior section of the uterus pressed down in front of it, so that craniotomy would have been an extremely difficult operation. It seemed to us both that, even although there had been a great deal of manipulation, craniotomy under the circumstances would be such a serious thing, that Cæsarean section offered the better chance of saving the mother's life.

DR. F. A. HIGGINS presented a paper entitled

MY EXPERIENCE WITH ANTISTREPTOCOCCUS SERUM IN PUERPERAL SEPSIS.[2]

DR. BOLAND: I have seen this treatment used in only one case, and that in the practice of a neighbor. The physician was warned by the patient that she always had childbed fever, and he was especially careful. But the symptoms developed. The temperature ran to 104° F. There were tympanites, delirium, weak pulse; in fact, all the classical symptoms. He curetted, stimulated, employed intra-uterine injections and used antistreptococcus serum. The effects Dr. Higgins spoke of, namely, temporary depression of the pulse and temperature was noted. This treatment was finally discontinued and the woman made a good recovery. Evidently she responded more to stimulation than to the serum treatment. Until bacteriology determines just what the pathogenic agent is, and that we have nothing to deal with but that single infection, it seems to me any deductions from the use of antitoxin must be fallacious. I fully agree with what Dr. Marcy has said as to the caution we should use in our predictions of any form of treatment.

HOSPITALS IN JAPAN.

WE ordinarily think of Japan as a country in which all the refinements of civilization are firmly established. Before analyzing the facts it is not a little surprising for us to learn, therefore, on the authority of Dr. E. C. Register, writing in the *Charlotte Medical Journal*, that there are but 10 notable hospitals in the entire country, with its population of 45,000,000. Some cities with a population of 100,000 have no hospital, and the very largest cities are far from liberally supplied. Tokio, for example, has only two, one of which, however, cares for about 2,200 patients a year, outside of out-patient departments, and has a staff of 80 resident physicians and 600 trained nurses. It is at this institution that Dr. Kitasato has his laboratory.

Surgery is done throughout Japan with much skill and success, but under considerable difficulty, owing to the deeply rooted prejudice among the people against surgical operations, due in great measure to the influence of the teachings of Buddhism. The prejudice is being slowly overcome, but still, in this hospital the amount of surgery is relatively less than work done in the departments of medicine. A striking feature of the hospital is the amount of tuberculosis treated in its wards. At the time the paper was written from which we quote, 40% of the patients had tuberculosis, and the records for the preceding five years show that 35% of all cases admitted were tuberculous. Tuberculosis appears in general to be very prevalent among the Japanese, no doubt due in great measure to their manner of life. Statistics show that 32% of all deaths in Japan are due to this disease. Skin diseases are correspondingly rare, no doubt due to the great cleanliness and bathing propensities of the people.

In Yokohama there is but one small and poorly equipped hospital, and Kiota, the former capital

of Japan, with a population of some 600,000 has only one good hospital, which is combined with a medical school. Pharmacy and medicine are both taught, partly by native and partly by foreign teachers, and last year 21 students were graduated. Other large cities are usually provided with but one hospital. Of the hospital at Kobe, Dr. Register writes as follows: "Its buildings are very large and it is evidently well patronized. They have 80 trained nurses, and an average of 250 patients. Its reception rooms for out-door patients were crowded to overflowing. The general operating room for third-class patients interested me more than anything surgical I have seen in Japan. Here 7 operations in one room were being performed at one time. It reminded me of Barnum's circus, it had so many attractions going on at one time. It had no preparatory ante-room for undressing or dressing. The anesthetic was administered and, in fact, everything connected with each case was done in this one room. Female as well as male patients were admitted and treated or operated on as their time came. I noticed one surgeon was operating for urethral stricture in the male, another setting a broken arm for a little boy, while another was doing gynecological work."

The medical centre of the country is the Imperial Hospital at Tokio. The distances from other parts of the country are comparatively small, and it has therefore become the custom for patients with complicated diseases to resort to it for treatment. The general impression one gets from Dr. Register's interesting paper is that Japan is in no way behind in the methods of surgery and medical treatment, but that it has not yet seen the necessity of multiplying institutions, a fact which we certainly cannot forthwith regard as unprogressive.

TWO PUBLIC DOCUMENTS.

WE have before us the yearly reports of the Pauper Institutions Department and of the State Board of Insanity. Both show that material progress has been made in the care and classification of the charges coming under the jurisdiction of the two boards.

At Long Island the hospital department has had a renewed stimulus given it in the establishment of a pathological laboratory. On this point the report of the Visiting Medical Staff reads: "No one thing has conduced more toward the rapid development of the hospital than the establishment of an adequate laboratory under the immediate direction of a salaried pathologist. It is now possible, for the first time in the history of the institution, to afford the sick the advantages which come directly and indirectly from modern laboratory methods of diagnosis and research. We are confident that the experience of this hospital will be like that of others, in which working laboratories have been established, in creating enthusiasm, fostering observation and accuracy, and thereby leading to the more intelligent treatment of the patients." The immediate future is also likely to see at this hospital the building of a nurse's home and a large model ward for the special care of tuberculous patients. In this ward the possibility of a city hospital for chronic consumptives is foreshadowed. In general this report shows that progress towards an adequate hospital for the treatment of chronic disease is being made, a fact which we note with gratification.

The State Board of Insanity in its report presents in clear form the problems to be met, and offers many admirable suggestions regarding classification and the more adequate treatment of the various types of mental disease. In view of the gloomy reports of the supposed increase of insanity which from time to time reach us, the following conclusions are of interest: That the increase of registered insane does not necessarily imply an increase of occurring insanity out of proportion to the growth of population; that the rate of increase of occurring insanity is certainly much less than the apparent increase of the insane; that there is a marked and growing tendency to commit all classes of the insane to institutions, especially in the case of old people, of the feeble-minded and of criminals; that a thorough inquiry into the specific causes of such tendency should be instituted as soon as possible.

To those interested in social problems, as well as in disease simply from a medical point of view, we cordially recommend a careful perusal of this scholarly report.

DEFEAT OF THE BILL TO REGULATE VIVISECTION.

WE note in another column the fact that the bill recently introduced into the legislature to regulate the practice of vivisection in Massachusetts was rejected without argument on the adverse report of the committee. Extended comment is unnecessary. To those who followed the discussion as presented at the State House, there could be no surprise at the final attitude of the committee. The same arguments, differently worded, that always have been, and always must be used, were employed, statements of fact on the one hand, and sentimentalism on the other. Unfortunate as it is that the world is so constituted that progress in medicine must be made by the sacrifice of animal life, the fact remains that such is the case, and that our knowledge of disease and its causes is likely in the future to be more and

more dependent upon this sort of experimentation. It is a hopeful sign, therefore, that the legislative committee, before whom the question was this year argued, was judicial rather than sentimental, and voted, as they in reason were obliged to, against a restrictive legislation, which would have been far-reaching in its harmful influence on the development of scientific medicine throughout the State.

MEDICAL NOTES.

The Woman's Hospital of Manila. — This hospital, which was founded on January 16, 1901, by a gift of $5,000 from Mrs. Whitelaw Reid, of New York, was designed to afford a suitable place for the care of cases of sickness and confinement, affording suitable facilities for the care of those able to pay, which was previously wanting in the city. A suitable house and premises were secured on February 16th, situated on Ceurval Solano in San Miguel, and having a water front on the Parig, thus making the hospital accessible by land and water transportation. Five trained nurses are employed. Miss Mary E. McDonald, a graduate of Bellevue and former chief nurse in the army service, is superintendent. The hospital is fully equipped, has "every modern appliance" for the care of the sick and is lighted by electricity. The hospital is under the charge of a board of eight trustees, and there are thirteen members on the Board of Consulting Physicians and Surgeons. Dean C. Worcester is president of the board of trustees. Such an institution must be of inestimable value to foreigners needing surgical or medical care in Manila. A directory for nurses is also a useful adjunct to the hospital.

Christian Science in Georgia. — It is reported that Judge Lumpkin, of the Superior Court in Atlanta, Ga., has ruled that Christian Scientists cannot practice their treatment of disease in Georgia without having been regularly graduated in medicine, or having passed an examination before the medical examining board, as is demanded of physicians. He furthermore holds that, according to the decision of a case in the Supreme Court of Nebraska, Christian Science is the practice of medicine, and that the practice of medicine in Georgia, according to the State law, must be done by persons who are regularly graduated from a medical school.

Plague in Various Places. — An investigation by the Marine Hospital Service shows the undoubted presence of plague among the Chinese in San Francisco, from which a few deaths have occurred. A recent estimate of the prevalence of the disease in Cape Town, South Africa, showed that altogether there have been 455 cases of the disease, of which 113 patients have been Europeans, and that the total number of deaths has been 185, including thirty-two Europeans. New cases continue to be reported, both among Europeans and natives. According to Hong Kong advices, 18,000 people have died of plague in the Lamko district of Hai Nan Island during the past few months.

Precautions Against Plague in Canada. — Special precautions are being taken to prevent the introduction of plague and smallpox into Canada. Orientals entering by way of the Pacific are compelled to undergo a bath at the quarantine station, and their clothing and effects are disinfected. Officers have been appointed to watch the boundary between Canada and the United States, and all suspected cases of smallpox are ordered into quarantine.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, May 1, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 68, scarlatina 19, measles 138, typhoid fever 9.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending April 27th was 246, as against 237 the corresponding week last year, showing an increase of 9 deaths, and making the death rate for the week 22.88. The deaths from consumption were 18, pneumonia 46, whooping cough 4, heart disease 27, bronchitis 3, marasmus 3. There were 5 deaths from violent causes. The number of children who died under one year was 55; under five years 76; persons more than sixty years 46; deaths in public institutions 82.

Suit for Alleged Injury from X-Rays. — A suit of $15,000 has been brought by a woman in the Superior Court at Salem, Mass., for alleged personal injuries received while undergoing x-ray examination for the purpose of diagnosticating an intra-abdominal disorder. It is claimed by the plaintiff that after three exposures of twenty, forty and fifty minutes, a blister appeared, which has not healed. This is said to be the first case of the kind which has come to trial in Massachusetts.

Failure of Bill for Restriction of Vivisection. — The Senate has accepted without debate the adverse report on the bill in further restriction of the practice of vivisection.

A Centenarian. — Mrs. Eunice Russ (Ames) Davis, the oldest resident of Dedham, Mass., died April 26th. She was born in Andover, October 26, 1800, making her at time of death one hundred

years and six months of age. Her mother is said to have been a full-blooded Narragansett Indian. She is survived by eight grandchildren.

NEW YORK.

Official Changes under the Amended Charter. — Among the changes of special interest to the medical profession effected by the amended charter of the city, which was passed by the legislature over the veto of Mayor Van Wyck and signed by Governor Odell, are the following: One Commissioner of Charities will succeed to the duties of the present board of three commissioners, and on February 1, 1902, the care of Bellevue Hospital, the Gouverneur, Harlem and Fordham Hospitals, and the Emergency Hospital will be transferred from the Department of Charities to a board of trustees, to be appointed by the mayor. The Health Department is to consist of one commissioner, appointed by the mayor, the police commissioner and the health officer of the port. At present there are five members of the Board of Health, a president and two commissioners (all appointed by the mayor) the police commissioner and the health officer. The powers of the Health Department, in respect to the supervision and inspection of tenements, are transferred to the new Tenement House Department, which will also have authority to regulate the construction or alteration of tenement dwellings.

The New York County Medical Association. — At the annual meeting of the New York County section of the New York State Medical Association, held April 15th, the following officers were elected: President, Dr. Parker Syms; First Vice-President, Dr. Alexander Lambert; Second Vice-President, Dr. Francis W. Murray; Recording Secretary, Dr. Ogden C. Ludlow; Corresponding Secretary, Dr. Montefiore L. Maduro; Treasurer, Dr. Charles E. Denison.

Smallpox at Foundling Asylum. — On April 24th 7 cases of smallpox, one of the patients being a nurse, were reported from the New York Foundling Asylum, on Third Avenue, making 17 cases of the disease in the institution within two weeks. It seems very difficult to understand why so much smallpox should develop among the inmates of such an institution, where it can scarcely be doubted that careful vaccination is very rigidly enforced.

The Society for Medical Jurisprudence. — The eighteenth annual banquet of the Society of Medical Jurisprudence was held at the Waldorf-Astoria on April 21st. Dr. Frank Ferguson presided, and among the toasts responded to were, "The Future of the Municipal Government and the Doctor and the Lawyer in It," by Judge Wm. J. Gaynor, and "Lawyer and Doctor," by Dr. Wm. M. Polk.

Miscellany.

REPORT OF JOINT COMMITTEE OF STATE CHARITIES AID ASSOCIATION.

A continuation of the happy results previously reported is shown in the report for the third fiscal year of the Joint Committee of the State Charities Aid Association and the Association for Improving the Condition of the Poor, which was formed in the interest of the children in the city's Infant Hospital on Randall's Island. The report of the New York County visiting committee of the State Charities Aid Association, in December, 1897, showed that of 366 infants under six months old admitted to the hospital during 1896, but 12 remained alive on April 15, 1897, a mortality rate of 96.7%. The joint committee, then organized, submitted to the Commissioner of Public Charities an offer to transfer a certain proportion of the infants to carefully selected boarding homes in the country, and the commissioners accepted the offer, agreeing to pay $2.00 per week per capita toward the board of the children, the committee to meet the additional expense. The work was begun in April, 1898, and the mortality among the infants thus boarded under the care of the committee has been as follows: During the years ending March 31, 1899, 55%; March 31, 1900, 31.1%; March 31, 1901, 18.9%.

In the providing of good permanent homes by adoption the committee has been equally successful, and during the three years a rapidly increasing number of children have been so placed. It has been found with surprise and pleasure that there are large numbers of childless families — many of them in very comfortable circumstances — who are not only willing but anxious to receive these unfortunates as their own.

Obituary.

WILLIAM H. DRAPER, M.D.

The death of Dr. William H. Draper, of New York, was announced April 26th. He was born in Brattleboro, Vt., October 14, 1830, was educated at Columbia College, and was also graduated in medicine at the College of Physicians and Surgeons. After serving at Bellevue Hospital, he studied in London and Paris. Returning, he became clinical professor of diseases of the skin at the New York College of Physicians and Surgeons in 1869, professor of clinical medicine in 1880, and professor emeritus in 1898. He was a trustee and also president of the College of Physicians and Surgeons before it was merged with Columbia, and he was a trustee of Columbia University from 1889 until his death. In the New York Hospital his service covered a period of thirty-nine years. He was first appointed physician in 1862, and in 1893, after four years as consulting physician, he resumed the more active work, and so continued until a year ago. Then he was again retained as consulting physician. He was attending physician at Roosevelt Hospital from the time of its organization in 1871 until he resigned and became consulting physician in 1897. He was also connected with St. Luke's, the Presbyterian and Trinity Hospitals and other institutions. He was president of the Academy of Medicine in 1886. Both as a man and as a physician

his death comes as a distinct loss to the community in which the greater part of his life was spent.

For many years Dr. Draper was one of the most esteemed consultants in New York. To unusual ability and skill were added the utmost refinement and a delightful charm of manner. Aside from his profession, he was a man of high attainments, and he was always an appreciative and liberal patron of music and art. He leaves a wife and eight children. His oldest son, Dr. William K. Draper, has for some time been associated in practice with Dr. Francis P. Kinnicutt.

Correspondence.

STATUS OF THE LAWS AND REGULATIONS IN REGARD TO IMPORTATION OF SURGICAL INSTRUMENTS BY HOSPITALS.

BOSTON, April 26, 1901.

MR. EDITOR: — I send you the following in regard to the importation of instruments by hospitals, as it seems to me that it will interest a certain class of your readers, and I will take for example the importations which have been made by the Massachusetts General Hospital.

Prior to July 24, 1897, and by the Customs Administrative Act of 1890, the law read:

INSTITUTIONS. — Philosophical and scientific apparatus, instruments and preparations; statuary, casts of marble, bronze, alabaster or plaster of Paris; paintings, drawings and etchings, specially imported in good faith for the use of any society or institution incorporated or established for religious, philosophical, educational, scientific or literary purposes, or for the encouragement of the fine arts, and not intended for sale . . . . .

Before this law was changed, the Massachusetts Hospital had on several occasions imported surgical instruments and surgical glassware without any question of duty. They were always entered free. All of a sudden one of their importations of glassware and instruments was held up for duty on the ground that they were not scientific or philosophical instruments; that the surgical instruments were tools and the glassware was glassware. The hospital paid the duty under protest and argued the case before the Board of Appraisers in New York, producing witnesses and drawings of various instruments. The Board of Appraisers in New York sustained the decision of the collector, maintaining that the exhibit was not one of scientific and philosophical instruments. The hospital then appealed to the United States Circuit Court and the case was argued before Judge Colt, who decided, briefly, that they were scientific and philosophical instruments and as such were intended to be, by law, free from duty. The Treasury Department appealed from this decision, and the case was again decided in favor of the hospital by Judge Lowell, and the duties paid under protest were refunded; all this after a litigation of about three years, if my memory is correct.

The next importation of instruments which occurred after July 24, 1897, was also held up for duty, and it appears the law was changed by the revision of the tariff which went into effect in 1897, and the law read as follows:

INSTITUTIONS. — Philosophical and scientific apparatus, utensils, instruments and preparations, including bottles and boxes containing the same, specially imported in good faith for the use and by order of any society or institution, incorporated or established *solely* for religious, philosophical, educational, scientific or literary purposes, or for the encouragement of the fine arts, or for the use or by order of any college, academy, school or seminary of learning in the United States, or any State or public library, and not for sale, subject to such regulations as the Secretary of the Treasury shall prescribe . . . . .

the important change in the law being in the insertion of the word "solely"; "solely for religious, philosophical, educational, scientific or literary purposes." Duty was paid under protest on this importation and the case was argued before the Board of Appraisers in New York. They decided in favor of the Collector of the Port, on the ground that the Massachusetts Hospital was not established or incorporated as a seminary of learning or solely for scientific or literary purposes, and in fact, did not come under the head of Institutions which were intended to be exempt. The case was appealed and came up before Judge Colt again, in the United States Circuit Court. Judge Colt stated that the Massachusetts Hospital in effect did not come under the heading of these institutions which were intended to be exempt. The hospital, therefore, paid the duty and this is the present state of the laws regarding importation of instruments and utensils by hospitals.

I do not believe that the framers of this tariff really intended to exclude hospitals from the benefit of free entry when they were willing to allow "libraries, institutions of learning, religious, philosophical or fine arts institutions," to import free, and I feel very sure that if some effort were made to have this law repealed, it could be done without much trouble; and it seems to me the way to do it would be to have the representatives of every hospital write to their congressmen and call their attention to the fact that the law, previously in their favor, has been changed, and that it is a hardship which other institutions of a similar nature do not have to put up with, and that they request the law be changed to the old law before 1897.

Yours very truly,
C. G. WELD.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 20, 1901.

Deaths reported 2,375; under five years of age 708; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 568, acute lung diseases 372, consumption 305, diphtheria and croup 65, diarrheal diseases 50, scarlet fever 49, influenza 2, typhoid fever 26, whooping cough 14, measles 15, cerebro-spinal meningitis 8, smallpox 10.

From whooping cough, New York 3, Pittsburg 2, Boston 2, Lowell 2, Chicopee 2, Worcester 1, Holyoke 1, Ever-

ett 1. From cerebro-spinal meningitis New York 4, Baltimore, Worcester, Lowell and Springfield 1 each. From scarlet fever, New York 37, Pittsburg 2, Boston 8, Cambridge 1, New Bedford 1. From typhoid fever, New York 13, Pittsburg 9, Boston 2, Fall River 1, Lynn 1. From measles, New York 10, Boston 4, Somerville 1. From smallpox, New York 10.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,089, for the week ending April 6th, the death rate was 19.2. Deaths reported, 4,341; acute diseases of the respiratory organs (London), 360, whooping cough 109, diphtheria 64, measles 105, fever 22, scarlet fever 39.

The death rate ranged from 9.7, in Croyden, to 27.7, in Liverpool; Birkenhead 11.8, Birmingham 24.2, Blackburn 19.9, Bolton 22.0, Bradford 22.1, Brighton 12.5, Bristol 20.0, Burnley 19.5, Cardiff 16.2, Derby 17.6, Gateshead 24.1, Halifax 22.4, Huddersfield 20.8, Hull 15.9, Leeds 18.4, Leicester 18.6, London 17.6, Manchester 24.3, Newcastle-on-Tyne 16.9, Norwich 18.8, Nottingham 21.2, Oldham 17.7, Plymouth 15.6, Portsmouth 14.1, Preston 18.2, Salford 24.7, Sheffield 19.8, Sunderland 23.4, Swansea 18.0, West Ham 13.6, Wolverhampton, 24.8.

METEOROLOGICAL RECORD.

For the week ending April 20th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

SOCIETY NOTICES.

AMERICAN LARYNGOLOGICAL ASSOCIATION. — The twenty-third annual congress of the American Laryngological Association will be held in New Haven, Conn., May 27, 28, 29, 1901.

NEW HAMPSHIRE MEDICAL SOCIETY. — The one hundred and tenth anniversary meeting of the New Hampshire Medical Society will be held May 16, 17, 1901, in Concord, N. H.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — The last regular meeting of the society for the season will be held at Sprague Hall, Medical Library Building, Fenway, on Monday, May 6th, at 8.15 P.M.

Papers: Dr. E. G. Brackett and Dr. F. J. Cotton will present a short communication entitled "Intermittent Hydrops." Dr. C. H. Alden, U. S. A., retired, will read a paper on "the U. S. Army System of Personal Identification." Dr. Weston P. Chamberlain, U. S. A., will read on "The Medical and Sanitary Conditions in the Philippines."

ARTHUR K. STONE, M.D., Secretary,
657 Boylston Street.

RECENT DEATHS.

ROBERT WILLARD GREENLEAF, M.D., M.M.S.S., of Boston, died April 28, 1901, aged forty-five years.

LAWRENCE JOHN MCDONOUGH, M.D., M.M.S.S., died in Lowell, March 2, 1901, aged forty-two years.

DR. ROY INGLIS, of Jersey City, N. J., died of tuberculosis at Denver, Col., on April 23d. He was graduated from the College of Physicians and Surgeons, New York, in 1890.

DR. JAMES S. CARRADINE, of New York, died at East Orange, N. J., on April 23d, of pneumonia. He was born in Yazoo, Miss., and was graduated from the Pennsylvania Medical College in 1858. During the Civil War he served as surgeon in the Confederate Army.

DR. FREDERICK J. BROCKWAY, an assistant demonstrator of anatomy and Secretary of the Medical Faculty of Columbia University, died of meningitis on April 21st. He was born in South Sutton, N. H., February 24, 1860. He was graduated from Yale in 1883, and from the College of Physicians and Surgeons, New York, in 1887. Dr. Brockway has devoted his life to scientific work and teaching.

DR. RICHARD C. BAKER, a prominent physician of Williamsburgh, Borough of Brooklyn, N. Y., died at Otsego, Otsego County, N. Y., his birthplace, on April 24th, at the age of forty-seven. He was graduated from the medical department of the University of the City of New York in 1874, and during the administrations of Mayors Chapin and Boody was Secretary to the Brooklyn Board of Health. Dr. Baker was on the visiting staff of the Eastern District Hospital, Williamsburgh.

Contributions on Typhoid Fever.

SOME REPORTED CASES OF TYPHOID FEVER ATTRIBUTED TO CONTAMINATED OYSTERS, WITH CERTAIN FACTS CONCERNING THIS MEANS OF INFECTION.[1]

BY CHARLES HARRINGTON, M.D., BOSTON.

In 1880, Sir Charles Cameron[2] brought to the attention of the profession, that oysters, transplanted from the coast of the County of Wexford to the Northern shore of Dublin Bay, had for some years been much subject to disease and had died in large numbers. Specimens which were examined were found to contain sewage matters, and investigation showed that the beds "were literally bathed in sewage." He offered the suggestion that raw oysters, taken from the shore close to sewer outlets, were, perhaps, as likely to act as the vehicle of typhoid fever and other diseases as contaminated water or milk, and advised that "oyster beds should not be laid down at any point on or close to the mouth of a sewer." But the warning appears to have excited no more than a languid interest until 1893, when the late Sir R. Thorne-Thorne, in a report to the Local Government Board, stated his belief that the sporadic cases of cholera which had occurred at various inland places in England in that year were due to oysters and other shellfish from sewage-contaminated water at Grimsby, where there had been a small outbreak of the disease.

In the following year occurred the well-known outbreak of typhoid fever at Wesleyan University, which was so ably and conclusively traced by Professor Conn of that institution to polluted oysters. His report,[3] a model of etiological inquiry, has been very extensively reprinted and abstracted, but in view of the recently aroused public interest in the possible danger to public health from the consumption of polluted oysters, I venture to rehearse briefly the essential facts of the outbreak, which not only was the first, but stands today the most thoroughly investigated, as well as the most extensive, case of its kind.

On October 20, 1894, several of the students were reported as slightly ill, with a moderate degree of fever. The number of cases grew from day to day, and shortly included several of undoubted typhoid fever. By November 1st, there were 20 cases of the disease, which number was shortly further increased to 23. All of the victims were of the male sex; there was no illness among the fifty-eight women students. Investigation completely absolved the water supply, the general and particular food supplies of the various boarding places, and the local conditions of the dormitories and outside lodgings of any suspicion of blame. It appeared that nearly all of the victims were members of three of the seven college fraternities. The combined membership of the three was about one hundred. On October 12th, eight days before the development of the first symptoms, all seven fraternities had had their initiation ceremonies and had celebrated in the usual way with a supper. Investigation of the origin of the components of the suppers showed that there was but one dish from a common source, and that was oysters. The three afflicted societies and one other had obtained their oysters from a local dealer; of the remaining three, two had had no oysters, and the third had had some from a dealer in Hartford. Of the four supplied by the local dealer, one had eaten the oysters cooked, and its membership was not invaded. Thus the trouble became sifted down to the raw oysters from the local dealer. But there was one victim who was a non-society man, and, clearly, his case could not be traced to the initiation supper. Investigation of his dietetic history established the guilt of the local oyster supply even more securely, for it was shown that he had eaten raw oysters from the same lot at the shop of the dealer. It was learned, too, that 5 men from Yale had attended the exercises of the societies in which the outbreak occurred, and inquiry developed the information that 2 of the 5 were seized with typhoid fever some weeks after their return to New Haven.

Further investigation revealed the fact that the incriminated oysters had been brought from a bed from Long Island Sound, and, on October 10th, two days before use, had been stored in a bed at the mouth of the Quinnipiac River, a short distance (300 feet) from the outlet of a private drain from a dwelling, in which 2 persons, mother and daughter, lay ill with typhoid fever.

Shortly after the publication of this case, Sir William Broadbent,[4] published the facts of a number of cases of typhoid fever, seen by him in consultation with several practitioners, which appeared to be connected with the ingestion of raw oysters, although no absolute proof was adduced, the evidence being purely circumstantial. His cases follow:

Case I. On November 12th, he saw a young woman who had been confined a month previously and had made a good recovery. The water and milk which she had taken had been boiled; the sanitary arrangements of the house were perfect; no other inmate of the house was sick in any way. In the course of her convalescence she had eaten some oysters, and ten days later she came down with typhoid fever of an unusually severe type, from which she did not recover.

Case II. On November 19th, he visited two young men, living in the same house, in which no other person was sick. Both the house and the place of business where both were employed were in good sanitary condition. They had been seized, simultaneously, with typhoid fever of an unusually severe form, for which there was no apparent cause, except that ten days before the appear-

ance of any symptoms they had had an oyster supper together. Both cases terminated fatally.

CASE III. On November 23d he saw a young woman, who, ten to fourteen days previously, had on two occasions eaten a half dozen oysters with a cousin of about the same age. She had a mild case of the disease, as did also the cousin, who in the meantime had gone to Italy, where she was seized.

CASE IV. On November 27th, he saw a man and wife who had come down with the disease at the same time in a house which was sanitarily perfect. No possible cause was apparent, other than the fact that, two weeks before, they had indulged in oysters. At the same time, he heard of a case of a child of eight years in a house in which no other person was sick, and for whose illness no other reason could be given than that, shortly before being attacked, he had eaten a dozen oysters at the house of some friends.

CASE V. On December 6th, he saw a young man who had been sick for three weeks with influenza and bronchial catarrh. He had partaken freely of oysters and had developed typhoid fever. No other person in the household, which was a large one, had been seized.

CASE VI. Early in December he had been called to the country, where typhoid fever was unknown, to see a clergyman and his daughter, twelve years of age, who were suffering from the disease. The sanitary condition of the house was good, and no other member of the household was sick. Inquiry showed that about two weeks before they had twice had oysters from London, and that they alone had eaten them.

Following the report of Broadbent's cases came a communication from Sir Peter Eade,[5] who called attention to the mussel as well as the oyster as a means of spreading typhoid fever, and mentioned having lately seen a case of the disease supposedly due to oysters, eaten ten or twelve days before the initial symptoms, while on a visit to London. A little later, Dr. H. J. Johnson-Lavis[6] related certain facts which he had noticed while in practice at Naples in 1879. Gastro-intestinal disorders were especially prevalent among strangers. They varied in intensity from evidence of simple irritation to the most severe forms of typhoid fever. He noticed that, whenever he and his wife ate oysters, they suffered from colic, diarrhea and tenesmus, and that gastro-intestinal symptoms in his patients very commonly followed eating raw oysters. These cases included chronic gastro-intestinal disturbances, very stubborn in character, and typhoid fever, often of a very severe type. He noticed, too, that though no sickness was caused by oysters at the several places along the Italian coast from which the Naples supply was obtained, when they were brought to Naples and kept for weeks and sometimes months in the harbor in a bed less than sixty feet removed from the outlet of one of the main sewers, their use was by no means unattended by risk. At this place, individual dealers stored their oysters in baskets, which were pulled up through the filthy water as occasion demanded. Some of the oysters were examined. They yielded evidence of sewage in the water between their shells.

Dr. Arthur Newsholme,[7] medical officer of Brighton, England, reported that, during 1894, 83 cases were reported to him as typhoid fever. In 15 instances, the original diagnosis was found to be incorrect, and an equal number were found to be imported cases. He investigated the probable causes of the remaining 53 cases, and decided that no less than 15 were due to oysters, and 6 to other contaminated shellfish (clams, cockles and mussels). In other words, 40% of the genuine cases of typhoid fever were due to these articles of food. In a later communication,[8] after a thorough examination of the cases occurring during a period of four years, he reported the percentages of cases probably due to oysters and mussels as follows: In 1894, 38.2; 1895, 33.9; 1896, 31.8; 1897, 30.7.

Chantemesse[9] relates the following case. There had been no case of typhoid fever in the little village of l'Herault Saint André de Sangonis for about a year, when, on February 15th, a shopkeeper received a consignment of oysters from Cette. The entire lot was consumed by 14 persons, all of whom were made sick. In the six dwellings in which the victims lived, no other inmates were sick in any way. Eight of the number were made only slightly ill, the symptoms, which included abdominal pain, vomiting, diarrhea, borborygmus, anorexia and general malaise, lasting but two or three days. The 4 youngest, who ate but a few, were very sick for a much longer time (fifteen to twenty-five days), but recovered. The stools were very offensive, were passed with pain, and were dysenteric in appearance; there was tympanites with tenderness and gurgling. All 4 were greatly prostrated. The remaining 2, a young woman of twenty and a young man of twenty-one, developed very severe cases of typhoid fever. The young woman died.

To satisfy himself as to the probability of oyster infection, Chantemesse secured specimens from several sources (Marenne, Ostende, Portugal, etc.) and made bacteriological examinations. They yielded an abundance of bacteria and many were found to contain B. coli communis. He placed some of them in water intentionally infected with typhoid stools and cultures, and after twenty-four hours, removed them and kept them another like period before subjecting them to bacteriological test. They yielded the typhoid organisms and B. coli communis in great numbers.

Dr. Mosny,[10] to whom the French authorities referred the whole subject of mollusk poisoning for investigation, has reported a case in which 5 members of a family of 7, living in a village in a suburb of Paris, in which there had been no case of typhoid fever in four years, were made sick

after eating oysters sent to them from Cette. Four were seized in the evening of the following day with gastro-intestinal disturbance, which lasted twenty-four hours. On the eighteenth day, a youth of seventeen years developed unmistakable symptoms of typhoid fever, of which, nine days later, he died.

In March, 1897, Dr. T. Chatin [11] reported to the French Academy of Medicine the case of a family, of which several members were stricken after eating raw oysters from a bed which was contaminated by sewage matters. One member died. Many other such cases are to be found in foreign medical literature.

A very brief consideration of the viability of the typhoid and other organisms in the water retained between the shells and within the tissues of oysters and in sea water itself is now in order. The work of others than those quoted is merely confirmatory.

In 1889, De Giaxa [12] made a series of investigations of the influence of sea water on pathogenic bacteria, and found the following conditions to be favorable to growth and multiplication of microorganisms in harbor water: shallowness, stagnation and high temperature of surface water, abundance of vegetation, and admixture of sewage rich in organic matter. Certain pathogens were found to succumb very quickly to the influence of the ordinary species of water bacteria and others to be far less susceptible. Some were found to thrive well in sterilized sea water and retain virulence many days.

It was shown by Foote,[13] after the outbreak at Wesleyan University, that typhoid cultures, introduced within the shells of oysters from the bed from which the incriminated oysters were derived, were virulent at the end of forty-eight hours, which was the period which elapsed between the gathering and consumption of those which caused the outbreak. Furthermore, it was demonstrated that if the specimens were kept at 57° F., the organisms were active as long as a month later.

Dr. Joseph Polak,[14] of Warsaw, examined oysters from Ostend, Holland and Odessa, and concluded that, during transportation, the life processes have an undoubted inimical influence on bacteria, diminishing, and in certain cases, abolishing them completely. His conclusions were distinctly opposed to those of others who had determined that the typhoid fever organism lives longer in the tissues and juice of the oyster than in the sea water itself.

Klein detected B. coli communis in oysters from typhoid-infected beds, and has found that oysters, kept for a time in sea water intentionally infected with bacillus typhosus, yield the organism after four to eighteen days. Cholera bacteria were demonstrated in an active state after four to eighteen days. Wood subjected oysters to cholera-infected sea water and found the bacteria at the end of eighteen, but not after twenty, days.

According to Boyce, the typhoid organism will not grow in the tissues of the oyster, and, in fact, perishes rapidly therein if the oysters are removed to pure sea water. But, according to Klein and Foote, the organism lives, multiplies, and is virulent for a long time if the oysters are stored in polluted water. Klein found it virulent after three weeks, and Foote reported that, during the first two weeks of immersion in typhoid-infected water, it multiplies in the tissues of the oyster and then diminishes, but can still be found after thirty days. Other observers have found the bacteria of cholera and typhoid fever, B. coli communis, B. proteus vulgaris and other organisms, in oysters contaminated by sewage, and all unite in the opinion that the presence of B. coli communis should arouse suspicion and induce improvements in the management and supervision of oyster beds.

In the investigation of outbreaks of typhoid fever supposedly due to oysters, bacteriological proof of specific infection of those eaten or of others from the same lot always has been and always will be wanting, since, long before the appearance of the first symptoms of the disease, the material is no longer available for investigation. But, in view of the fact that pathogens have been found in the water between the shells of oysters from polluted beds; that they have been known to live for days in the tissues and retained water; and that, in the cases investigated, the beds have been found to be exposed to the influence of sewage, we may properly conclude that a causal relation is very possible.

The danger of infection arises wholly from the presence of sewage in the water where the oysters are planted or stored. The remedy lies either in transferring the beds to cleaner situations or storing the contaminated oysters in clean sea water until the bacteria have either perished or been washed away. What constitutes a sufficient length of time to insure purification is a matter of some disagreement. Many believe that a week is enough; others, that sixteen days should be allowed. They should not be stored where sewage matters can reach them through long distances by currents along the shore, nor where the prevailing winds can exert a harmful influence to the same end.

For a very thorough discussion of the subject of the proper management and supervision of oyster beds, the reader is referred to the exhaustive report of Dr. Mosny on the general subject of mollusk poisoning, published in *Revue d'Hygiene*, December, 1899, January, February and March, 1900, to which I am much indebted for many of the facts above given.

A GIFT TO THE HOSPITAL OF AIX-LES-BAINS. — A daily paper is authority for the statement that J. Pierpont Morgan has donated $10,000 to the hospital of Aix-les-Bains, France, and that the municipality has shown its appreciation of the gift by presenting him with a "magnificent bouquet."

EXPERIENCE WITH THE WIDAL REACTION IN TYPHOID FEVER.[1]

BY CHARLES F. WITHINGTON, M.D., BOSTON,
Visiting Physician, Boston City Hospital.

THE general experience of the last four or five years tends to confirm the favorable impression of the value of the Widal reaction as a diagnostic sign in typhoid fever. The usual percentage of 95% of successful results indicates, certainly, a valuable diagnostic aid. The limitations of the test, however, as to the time of its first appearance, which is rarely before the sixth day, and often not before the ninth or tenth, are such as to deprive it of the value which one would like to attach to it for early diagnosis.

In the earlier years of its employment in the City Hospital, the failures which were noted were open to the criticism, in some cases, that insufficient numbers of tests were made. For example: the test would be applied on the patient's entrance and once or twice afterwards, and such cases were erroneously construed as failures of the Widal reaction.

During the last year, it has been the custom to perform the test more frequently than at first, and it has been found that while the reaction sometimes appeared at a very late period—twenty or twenty-five days from the onset of the fever—nevertheless it was generally eventually obtained.

The method of applying the test has been the following: A few drops of blood have been drawn from the patient's ear into a small section of glass tubing, sealed at one end by heat and left open at the other. After the serum has separated, 1 drop of it is mixed with 10 drops of an active culture of typhoid bacillus, twenty-four to thirty-six hours old. The dilution is, therefore, 1 to 11, or 9%. For a control, a few drops of the unmixed culture is usually put on the other end of the slide. If immobility and clumping are present in the serum culture mixture in course of one-half hour, the reaction is reported as positive, otherwise not. In the majority of cases the reaction appears in ten or fifteen minutes.

With the assistance of my house officer, Dr. H. H. Smith, I have been able to present the results of Widal examinations in all the cases of typhoid fever at the City Hospital during a period of six months, from May 28 to November 28, 1900. There were during this period 253 cases of typhoid fever in the hospital which were tested, repeatedly, by the Widal reaction, in all cases until a positive result was obtained. In 10 of these cases there was a constant absence of Widal reaction, or 4% of failures.

In Case I, which was under observation only three days during the fifth week of the disease, the Widal proved negative 3 times.

In Case II, the Widal was absent 10 times, first on the twelfth day, last on the thirty-third day of the disease.

In Case III—a case fatal from perforation on the twelfth day—it was absent in 4 tests.

[1] Read before the Clinical Section of the Suffolk District Medical Society, November 20, 1901.

In Case IV, it was absent 15 times between the tenth and fifty-fourth days of the disease.

In Case V, it was absent 7 times between the fourth and twenty-second days of the disease.

In Case VI, it was absent 12 times between the sixth and thirty-fifth days.

In Case VII, it was absent 6 times between the fifth and fortieth days.

In Case VIII, there were 14 negative tests; Case IX, 12; Case X, 11.

In all of the above cases, the clinical evidence of typhoid was satisfactorily conclusive, except in one where the diagnosis was from autopsy, and in which, during life, symptoms were uncertain. This case was, briefly, that of an Italian, speaking no English, who entered in an unconscious state without any history ever being obtained. There were no rose spots; size of spleen was doubtful; the abdomen was retracted; there was no diarrhea. In this case a lumbar puncture was made four days after entrance; fluid was clear and contained no organisms. The white blood count remained at 6,000 until the last day of life, when it arose to 14,000. The diagnosis remained in doubt, but the autopsy showed typhoid ulcerations, representing, in the opinion of the pathologist, the fourth week of typhoid fever. The spleen was enlarged, and cultures from the gall-bladder gave bacillus typhosus; the moderate leucocytosis may have been "terminal" or else due to a little abscess between the right lobe of liver and diaphragm.

Case II had many rose spots, spleen was palpable and the patient had intestinal hemorrhages.

Case III presents so many points of interest that I take leave to report it somewhat in detail. The patient, a boy of fifteen, entered September 7th, having had headache for twelve days, with watery greenish stools for a week. He kept about, however, till the day before entrance, when he went to bed and had epistaxis. Rose spots were present on the eleventh and the spleen was felt; temperature rather irregular. Widal tests negative on the second, fifth, eighth and tenth days. Plasmodia absent. The perforation occurred at 6 A.M. on the tenth day when patient was taken with sharp abdominal pain—general, not localized, without nausea or vomiting. One hour later onset of rigor lasting two hours. At 8.45 A.M. examination showed slight general distention with slight spasm, more marked in right lower quadrant. Temperature subnormal, pulse increased in rate, expression rather anxious and patient suffering considerable pain. Diagnosis of perforation made by Dr. Ames, in whose care he was. After administration of $\frac{1}{8}$ grain of morphia and $\frac{1}{150}$ grain of atropia patient's condition improved slightly. Heaters given and hot fomentations applied to abdomen.

At 9 A.M. seen by Dr. Lund and a few minutes later by Dr. Munro, who recommended transfer. Seen one hour later by Dr. Withington who confirmed diagnosis and recommended operation. Parents refused consent. At 12 (midnight). Patient has steadily grown worse, with rise of

pulse and temperature. Expression anxious, face rather pinched, complains of slight abdominal pain. Locally distension has increased, with marked spasm over whole abdomen. Considerable tenderness. Pulse poor.

September 16th (10 A.M.). Patient has had no nausea or vomiting, slept four hours during the night. Has had two stools since yesterday morning, both of which were well formed, light yellowish, without blood. General condition has grown steadily worse. Facies septic. Slight cyanosis. Abdominal distension more marked, with great rigidity and spasm, more marked on right.

September 17th. Since last note patient has grown steadily worse, though pain in abdomen is somewhat less. Abdomen excessively distended, tympanitic, resistant with general spasm. Facies pinched, anxious, slightly cyanotic, vomiting has been frequent and controlled only slightly by morphia. Died at 10.20 A.M.

The temperature dropped immediately after the perforation to 97°, but rose again to 102°. The white counts which were made during the fifty-two hours between perforation and death were interesting as showing the development of the peritonitis.

On September 15th, 9.20 A.M., whites, 8,800; 10.20 A.M., 14,300; 11.20 A.M., 8,600; 12.20 P.M., 12,800; 1.20 P.M., 10,600; 2.20 P.M., 8,400; 5.30 P.M., 10,600; 8.10 P.M., 14,300; 10 P.M., 13,000. On September 16th, 8.15 A.M., 20,000; 10 A.M., 22,200.

Case IV had a few rose spots, the spleen was felt and there were several intestinal hemorrhages. In this, as in all the previous cases, the temperature chart was characteristic of typhoid.

In Case V, the temperature curve was unusually brief, about twelve days, but the spleen was felt; there were headache, vomiting and chills at the outset; probable rose spots; plasmodia were absent and the case seems pretty certainly to have been typhoid.

In Case VI, the chart was also characteristic; no rose spots were seen; there was a low white blood count, and at the end of twenty-two days, phlebitis developed in the left leg, which recovered after two weeks.

In Case VII, there was a pneumonia at the outset, but the spleen was enlarged and a few probable rose spots were noted. The temperature subsided by the lysis typical of a typhoid fever.

The remaining cases were also fairly typical of typhoid, one of them, Case IX, having a phlebitis.

We have, thus, 253 cases of undoubted typhoid with 10 failures of the Widal reaction. But besides these, there were 6 other cases, in which, although the evidence is not perfectly conclusive, the diagnosis of typhoid was made, and they all seem to me to have been probably actual cases of the disease. In these the following number of negative Widals, respectively, was obtained: eleven, nine, five, five, nine, seven. For the reason that objection might possibly be made to the certainty of the diagnosis I have rejected them from the foregoing list; but if we were to include them, as we perhaps fairly might, we should have a total of 259 cases during six months, with a failure of the Widal reaction in 16, or a little over 6%.

A typical instance of the tardiness of the Widal response is illustrated in 1 case, where, after 8 consecutive failures, it was positive for the first time on the twenty-ninth day.

THE WIDAL REACTION IN TYPHOID FEVER.[1]

BY GEORGE B. SHATTUCK, M.D., BOSTON,
Visiting Physician, Boston City Hospital.

FOUR years ago I presented a paper on the "Serum Test in Typhoid Fever," at a meeting of the Association of American Physicians, when I reported and attempted to analyse 125 cases of typhoid fever (clinical) at the Boston City Hospital in which the Widal test had been used.

The conclusions drawn from those cases at that time were as follows:

(1) The serum reaction may be obtained toward the end of the first week of typhoid fever, but is both more pronounced and more usual later in the disease.

(2) It may be present without a relapse at the end of the fourth month.

(3) It may be absent one day and present the next.

(4) Of 125 cases of typhoid fever (clinical) the reaction was absent in only 1 case. In 2 cases it failed, but there was in each only 1 test, in 1 case on the twelfth and in the other on the eighty-second day.

(5) In 19 cases of other diseases clearly uncomplicated by typhoid there was no reaction.

(6) In 1 case, where the diagnosis must remain doubtful, although typhoid cannot be positively excluded, there was a reaction.

(7) In a number of difficult and perplexing cases the serum test was of distinct service in establishing or correcting the diagnosis.

(8) This test will probably prove itself a useful aid to clinical diagnosis, and especially in hospital practice.

Dr. Withington's series of 259 cases from the same hospital, at this later period and after further experience, is comparable with my previous series and therefore, to me, at least, of a double interest. To supplement his cases, drawn from the three medical services over a period of six months up to November 27th, I have gone over the cases of typhoid fever (clinical) in my own service for a little more than two months from November 27th last to February 1st, 25 cases in all. I see no reason to essentially modify the conclusions reached four years ago and above reported. Out of these 25 cases, 1, with a non-typhoidal chart and otherwise somewhat doubtful clinically, gave a positive reaction on the tenth

[1] Read before the Clinical Section of the Suffolk District Medical Society, February 20, 1901.

day; 1 case with a clinical diagnosis of typhoid—chart, rose spots, gurgling, tympanitic abdomen, no spleen detected, course of four weeks — gave 5 negative Widals at intervals, no positive reaction, and was discharged well.

One case not included in the above, entering after three weeks' illness with doubtful clinical symptoms, gave 1 positive reaction. Subsequent tests were negative. This patient had been in the City Hospital two years before with typhoid fever accompanied then by a positive reaction. He subsequently developed pulmonary gangrene and died.

Among the cases included in Dr. Withington's statement were 2 occurring in the first two months of my service at the hospital this autumn, which should be grouped with the last 3 cases reported as exceptional. One of these entered with a history of four days' illness. The edge of the spleen could be felt, the abdomen was tympanitic, there was gurgling in the right iliac fossa, and a few possible rose spots. The chart was typical of the last week of typhoid, the patient was discharged well at the end of three weeks. The clinical diagnosis was typhoid fever, but there were 8 negative Widals. The other case entered with a history of illness for eleven days. There were numerous rose spots, a doubtful spleen, a tympanitic abdomen; whilst in the hospital there were two hemorrhages from the bowels. The chart was typical of the last ten days of typhoid. The patient was discharged well three weeks from entrance. The clinical diagnosis was typhoid, but there were 8 negative Widals.

In all 5 of these exceptional cases there was a low white count and the plasmodium malariæ was excluded.

My recent service of four months at the City Hospital, therefore, may be summed up as offering a total of 62 cases, with a clinical diagnosis of typhoid fever; of these 3 failed to respond to the Widal test. One case not included in the above, with a doubtful clinical diagnosis, gave a positive reaction. One case also not included, and doubtful at first but subsequently developing a different disease, gave 1 positive reaction but it was also learned that he had undoubted typhoid fever two years before.

I also find among my notes the following exceptional cases on the same medical service of the same hospital occurring between July 15, 1898, and January 1, 1899, during which time there were 140 cases with a clinical diagnosis of typhoid fever.

CASE I. Seven negative Widals. Typical history and chart, epistaxis, rose spots, enlarged spleen and abdominal tenderness.

Diagnosis. — Typhoid fever.

CASE II. One positive Widal. History referable to thorax, no spleen, irregular temperature, tubercle bacilli found, later meningeal symptoms.

Diagnosis. — Tuberculosis.

CASE III. Positive Widal. Patient had malaria; plasmodium found. Died five days following admission.

Autopsy. — Enlarged and pigmented spleen and liver, no ulceration of Peyer's patches nor other typhoid lesions.

Diagnosis. — Malaria.

CASE IV. Positive Widal. Sudden onset, chills, yellow expectoration, pain in chest, consolidation of right lower lung, crisis on ninth day, normal temperature following.

Diagnosis. — Pneumonia.

CASE V. Two negative Widals. Soldier, indefinite history covering last two weeks, enlarged spleen, rose spots, symptoms of perforation, death.

Autopsy. — Typhoid perforation. Many ulcerated Peyers patches. Malarial pigment.

Diagnosis. — Typhoid with perforation.

CASE VI. One positive followed by 2 negative Widals. Transferred from surgical ward; only symptom, a pain in left lumbar region, later in abdomen. Three months later still in hospital, in gynecological service, with probable tuberculosis of kidney.

CASE VII. Five negative Widals, 1 positive after normal temperature for four days and well into convalescence. Two negative Widals were obtained after sharp hemorrhage from bowel. History of four weeks duration before entrance and in bed one week. Typical chart; symptoms: spleen, rose spots, hemorrhage.

Diagnosis. — Typhoid.

CASE VIII. Two negative Widals. In bed most of time for past four weeks, gave typhoid history, elevated temperature, much enlarged spleen which has diminished progressively, typical typhoid stools, dull, apathetic, gurgling in fossæ, temperature declined by lysis.

These dates covered the cases resulting from the Spanish War.

Many cases of "soldiers" having malaria gave positive reactions, but owing to the inability to disprove the occurrence of typhoid while at the South, they are not included.

MEANS OF INFECTION IN TYPHOID FEVER.[1]

BY E. N. WHITTIER, M.D., BOSTON.

DR. HARRINGTON'S paper is most acceptable and timely. He backs up his own opinion with a synopsis of the views of other and preceding observers; the joint conclusions carry conviction.

My own experience has made me very apprehensive regarding the course of typhoids occurring in families whose summers have been passed away from the city—rural and not urban in the source of the infection, imported and not native, malarial and not straight. The typhoid of city origin may be atypical and puzzling; care and restrictions may be as prolonged, but it is without the terror, the destructiveness, the lethal drift characteristic of country typhoids.

[1] Read before the Clinical Section of the Suffolk District Medical Society, February 20, 1901.

I doubt very much if we appreciate the great and good work of our brethren in the village and farm districts of our northern New England States, where the high potency of typhoid infection often resembles that of dynamized solutions, and the malignancy of the process is frequently fulminating in its short and deadly course.

Fall fever, a north-country name for typhoid, is more dreaded there than any other infectious or any contagious disease—smallpox alone excepted. The farm well must remain practically as it is; the hill-side spring and piping, the meadow brook and hydraulic ram—I have seen them all—are inoperable, to borrow a surgical term, for several months yearly in a region where the ground freezes post-hole deep on the farm of the milk producer; the vaultless privy and the kitchen cesspool will continue to menace the health of every family within their sphere of influence, until the dairy and its adjuncts receive the same care and supervision as that now given the cattle in the matter of tuberculosis. Milk infection and its results are too widely known to call for other remarks.

A single case of typhoid, high up on a mountain stream, the water supply of Plymouth, Pa., resulted in a thousand cases of typhoid and a fatality of 10%. The Spanish bullets at El Caney and Santiago were not more fateful in their course than the flies from the latrines and cesspools at Chickamauga in the camps of 1898.

Milk infection, water supply pollution and camp food infection by flies—these are widely known; not so, however, until recently, the subject matter of Dr. Harrington's paper.

I suppose the occasion for this discussion is to be found in the outbreak of typhoid in the Boston colony, summer residents at Marion, Cape Cod. Marion has a winter population of 500, that of summer is estimated to be between 1,400 and 1,500. The village is delightfully located on the western shore, the deep water side of Sippican Harbor, an arm of Buzzard's Bay, about two and a half miles long with greatest width of about one mile.

The village water supply is largely from artesian wells, each on the premises of the owners of the house lots. Late in September last, I saw the first of a series of cases originating in the village, on October 9th, the second, and on October 13th, the third; afterwards there were 2 other cases (but not among my people), all residents of Boston in the winter and within easy pistol-shot of Charlesgate East. How many other cases in families or of people from other cities no one knows.

One case originated at the northern end of the village, 3 at the southern, a mile away, and yet another midway between. Neither milk, nor water, nor food supply in any form were common to all. If it was true that the village market-man kept his greens bright and his vegetables fresh by water from a polluted well, it is also true that he did not supply the families of my patients.

There is no sewage system in Marion. Residences erected along the water-front drain down to the shore, few have cesspools, so that for a mile or more, houses, shops, fish markets, stables, academy and hotel pour their sewage into the incoming and outgoing tide.

Up to last fall the Marion oyster, native to the region, had been the pride and glory of the place; on the deep shell he had no superior; he came next after grace at all the good dinners the place is so famous for; whatever else was absent, he was present at all functions; he was introduced to guests as a desirable acquaintance.

A house party of 6 sat down to oysters on a blazer, 3 of the number had typhoid. A plain or even a fancy roast is mere child's play to a microbe that hibernates in a cake of ice and comes up smiling the next summer.

Blenkinsop's Cove, a mile or more long, on the eastern side of the harbor and about a mile across from Marion Village, had been the chief source of the supply for the summer trade, until in midseason the demand increased and emergency calls arose; then, for convenience in quick delivery, etc., the clean oysters from across the harbor were kept in storage in places polluted by filth and contaminated by sewage. The State Board of Health reports the bacillus coli communis in oysters taken from various places on the village side, none in oysters from Blenkinsop's Cove.

This Marion outbreak, of small proportions fortunately, nevertheless has had wide influence; but the oyster was not so much at fault after all. A Virginia ham soaking in such waters would afford an example of food infection.

EARLY DIAGNOSIS OF TYPHOID FEVER BY ISOLATION OF BACILLUS TYPHOSUS FROM STOOLS; CONCLUSIONS OF DR. L. REMY BASED ON THE USE OF HIS ASPARAGIN-LACTOSE-CARBOL GELATINE.[1]

BY CALVIN G. PAGE, M.D., BOSTON,

Assistant in Bacteriology, Harvard Medical School. Physician to Orthopedic Department, Boston Dispensary.

It is almost impossible to isolate the bacillus of typhoid fever from a mixture containing the common colon bacillus by means of plate culture with the ordinary nutrient gelatine or agaragar. This is not due to any antagonism between the two organisms, but is the fault of the culture medium. Many men have tried to invent a medium that could be used to separate the typhoid from the colon bacillus.

One of the most noted of these, Elsner, in 1895, successfully used a gelatine medium made from the juice of potatoes. Other observers failed to obtain his results on account of the great variations in the chemical composition of potato.

In 1896, a Belgian, named Rémy, devised a gelatine medium made with asparagin and definite amounts of several salts to correspond to a chemical analysis of potato. With this he successfully separated laboratory cultures of typhoid and colon bacilli, and later on cultures derived from stools

[1] Read before the Clinical Section of the Suffolk District Medical Society, February 20, 1901.

of typhoid patients. Just before using he adds to each tube of medium a little milk-sugar, and two drops of a 1–40 carbolic acid solution. The culture or feces is diluted twice, first about 1 to 40, second about 1 to 8,000. One or two loopfuls of this second dilution is mixed with a tube of melted medium and poured onto a glass plate. Colonies appear after two days at room temperature. The smaller and paler colonies are probably typhoid, but the appearance of the colonies is never sufficient for a diagnosis. Little cubes of gelatine containing each one colony are cut out and transferred to several tubes of bouillon. Examination of these tubes after a short incubation will show whether or no the organism is a motile bacillus. Some of it is then transferred to milk-sugar gelatine and incubated to see whether gas bubbles will develop. The bacillus must be tested with known typhoid serum to see if it will clump, and the bouillon culture tested for indol. If the bacillus clumps in the presence of typhoid serum and produces neither gas nor indol it may be said with certainty to be typhoid. If it does not clump and produces neither gas nor indol it may yet be typhoid, for typhoid bacilli when living together with colon bacilli may gradually lose their sensitiveness to typhoid serum. If gas is produced the culture is certainly colon bacillus.

Early in 1889 Rémy began to apply this method to the examination of stools of typhoid patients. During the year he made 31 examinations of stools from 23 cases of typhoid fever, and isolated the typhoid bacilli from every case. One examination was negative because the dilution was not sufficient, another because it was too great. Repetition in these cases, however, gave positive results. One case on the fifty-eighth day gave a negative result, though an earlier trial was positive. The earliest of all the examinations was on the third day of the disease, the latest on the forty-fifth day. Early in the disease the typhoid bacilli are present in relatively small numbers. They increase considerably during the second week, and may sometimes be almost the only bacterium present. During the third and fourth weeks the number diminishes steadily.

In two cases where an unusually large number of typhoid colonies developed on the plates, the patients died soon after the examination. In all the cases the typhoid bacilli had the same characteristics. They did not produce indol, they did not make gas from milk-sugar, and when mixed with typhoid serum they clumped promptly. The bacilli isolated during the second week grew rapidly and abundantly, while those isolated toward the end of the disease showed less vigor. In 3 cases the typhoid bacilli were found in the stools before the serum reaction or any other sign of typhoid fever was present. Consequently the presence of the typhoid bacillus with its specific characteristics is the only sign that, taken by itself, will justify the clinician in making a certain diagnosis. It is also the only sign that cannot fail. Control examinations of the stools from 12 patients with other diseases failed to show the typhoid bacillus. The constant presence of the typhoid bacillus in the stools of persons sick with typhoid fever and the absence of it in the stools of other patients, Rémy offers as additional proof that the bacillus is the true cause of the disease.

I have made three lots of gelatine after the formula of Rémy, but cannot yet give any conclusion based on personal experience. The time required to make a report is at least three days.

Those who have used a method described by Piorkowski say that it is valuable and worth further trial. McConkey working in the Thompson-Yates Laboratories, in Liverpool, has had very encouraging results by adding bile salts to a medium for separating typhoid and colon bacilli. There is, therefore, good reason to hope that a method will be devised by which a report of examination of feces can be made in less than three days.

THE FEVERS OF THE PHILIPPINES.[1]

A PRELIMINARY REPORT ON THE NATURE OF THE FEVERS PREVALENT IN THE PHILIPPINE ISLANDS, INCLUDING TYPHOID FEVER, MALTA FEVER, THE MALARIAL FEVERS AND UNDETERMINED TROPICAL FEVERS.

BY JOSEPH J. CURRY, M.D.,

Captain and Assistant Surgeon, U. S. V., Philippine Medical Service.

TYPHOID FEVER.

TYPHOID fever existed among our troops in the Philippine Islands to a considerable extent. There is hardly a command that has not lost men by it, still typhoid fever never has assumed anything near the epidemic form as occurred in the camps in the United States during the Spanish-American War, and as now prevails in the English Army in South Africa. Some cases of typhoid were undoubtedly brought over in the early expeditions from San Francisco to Manila, but it is more than probable that typhoid fever existed widely in the Philippines at the time of our occupation.

Our troops occupied many of the old Spanish camps. From these camps came a large number of the cases of typhoid fever. The camps at the

[1] Extract of a Report to the Surgeon-General of the Army, on the Diseases of the Philippine Islands. (By permission of the Surgeon-General.)

Deposito near Manila, and at Calamba on the Laguna de Bay, especially were the source of many cases. These places had been used by the Spaniards for military camps for years. At Calamba the disease assumed epidemic proportions. Here in March, in 1900, there occurred considerable of an epidemic in the two companies of the Forty-second Infantry stationed there. Out of 16 men of these commands in the First Reserve Hospital (Manila) on March 16, 1900, 14 had typhoid fever. In each case a positive Widal reaction was obtained. Later in May and June, two companies of the Thirty-ninth Infantry were stationed at Calamba, and typhoid occurred to a considerable extent among them.

Malarial fever and dysentery were also prevalent at Calamba. In every command that camped at Calamba, there occurred a number of cases of typhoid fever, of malaria, and of dysentery. These old infected Spanish camps have been the source of a great amount of sickness among our troops. It has been difficult, if not impossible, for military reasons, to avoid occupying such camp sites.

Typhoid fever undoubtedly existed among the Spaniards and natives before our occupation. To what extent it is impossible to state. The Spanish and native records as to the cause of death in Manila are absolutely worthless. Over 70% of the natives never see a doctor. Most diagnoses were made by the Spanish or native doctors after death, on the symptoms as described by the deceased's friends. Post mortems were practically never held save in the medico-legal cases under the Spanish régime. There was no pathological laboratory in Manila before the establishment of the army pathological laboratory at the First Reserve Hospital. In consequence, there is no reliable information to be had from the Spanish records. From information given me by both Spanish and native physicians, typhoid fever has existed for years in Manila. These physicians claim not to any great extent, but it is probable that typhoid fever was widespread before our arrival in Manila.

I performed one post mortem on a Chinaman who died at the San Juan de Dios Hospital in Manila. He died of intestinal hemorrhage. Autopsy showed typical lesions of typhoid fever, the post-mortem blood gave the Widal reaction, and the bacillus typhosus was obtained in cultures from spleen and mesenteric glands. This case had been diagnosed "tuberculose" by the attendant doctors at the hospital. At Calamba typhoid fever was found existing among the natives in a small barrio not far from the American camp. In one house located near a stream from which the soldiers were accustomed to drink, typhoid fever was found among the inmates, by Assistant Surgeon Lewis, U. S. Army, who was sent by the chief surgeon to investigate the cause of the typhoid epidemic in the two companies of the Forty-second Infantry.

We have abundant evidence that typhoid fever existed in and near Manila before our occupation. Out of the 20,081 medical cases treated at the First Reserve Hospital, 653 were typhoid fever. Of this number 93 died, a death rate of less than 15%. This is a remarkably low death rate for a tropical country and speaks highly for the Medical Department of the Army. This is less than one-half the death rate reported by the English Army surgeons for tropical countries (Manson). This low death rate is no doubt in part due to the *early recognition* of the disease *as typhoid*. The laboratory has rendered valuable service in this alone. There were 40 post mortems performed on this disease at the First Reserve Hospital from March, 1899, to June, 1900.

The immediate cause of death in over one-third of these cases was either perforation of the intestine or hemorrhage from the intestine. Among these 40 cases, death was due in 8 to a perforation of a typhoid ulcer of the intestine, and to intestinal hemorrhage in 5. In this series there was 1 case of typhoid fever without intestinal lesions, 1 of typhoid and estivo-autumnal malaria combined, and 2 of typhoid fever and amebic dysentery combined. In one of the latter there was also pulmonary tuberculosis, The study of these post mortems, and their complications, and the combined infections of typhoid fever in Manila, will be the subject of a special report later. It is instructive to compare the death rate among our troops from typhoid fever before and after the Philippine insurrection. From the occupation of Manila on August 13, 1898, to the outbreak of the insurrection early in February, 1899, there occurred 337 cases with 34 deaths, a mortality of practically 10%. From February, 1899, to June, 1900, there were 316 cases treated in the wards of the First Reserve Hospital, with 59 deaths, a mortality of nearly 19%.

One explanation of the higher mortality in this latter series of cases lies in the fact that these men, by prolonged subjection to fatigue of campaigns and the tropical climate, had less power of resistance than the troops fresh from the United States, with only camp routine duty to perform. That typhoid fever has not been more prevalent among our troops in the Philippines is remarkable. The great majority, if not all, of the regiments have had cases of typhoid fever, most of these had one or more fatal cases. With every opportunity for the spread of the disease, it is a great wonder that it has not assumed epidemic proportions before this. It is possible that the breaking up of the regiments into small commands and the frequent changing of camps is responsible for checking the spread of typhoid fever. No doubt some of the deaths reported as due to dysentery and to the malarial fevers were typhoid fever.

In stations distant from Manila it was not possible to have blood examinations performed, and then, too, it must be remembered that dysentery and typhoid fever may occur at the same time and the dysentery mask the typhoid. In the post mortems at the First Reserve Hospital there occurred 2 such cases. These men were admitted for dysentery, and the pronounced clinical symptoms were of dysentery.

The danger of the future is that when camps become more permanent that typhoid may increase among the troops. Typhoid fever is more severe in the tropics naturally than in a temperate zone. The mortality is normally certain to be twice as great. The prevention of typhoid fever among the troops in the Philippines is a serious problem. It was my intention before I left the Islands to request permission to try the prophylactic inoculation method which has been so favorably reported on by Wright and other English Army surgeons. The prophylactic inoculation method is worthy of serious consideration as to its adoption for troops departing for the Philippines and for those already there.

MALTA FEVER.

I had the honor to report to the Surgeon-General on January 2, 1900, 4 cases of Malta fever, which came under my observation at the First Reserve Hospital, and which originated on the Island of Luzon, P. I. In subsequent investigations 12 additional cases were found, in all of which repeated blood examinations were negative for typhoid, and for the malarial parasites, and a positive serum reaction with the micrococcus melitensis was obtained in a dilution of at least 1 to 60. The clinical history of each of these cases was that of a long-continued fever with periods of apyrexia, not influenced by quinine administered in large amounts. Typhoid symptoms were absent. Neuralgic and rheumatic symptoms were generally present and a general glandular hyperplasia existed.

It is to be regretted that more work could not be done on the study of this disease in the Islands. In March I was assigned to duty with the Manila Board of Health, and owing to my connection with the work on plague, I could not carry on my investigation on Malta fever.

The first case was found at autopsy July 26, 1899, by Assistant-Surgeon Strong. Corporal J. T. W., "G" Company, Fifty-first Iowa Volunteers, died after a long-continued fever diagnosed clinically as typhoid fever. At autopsy no lesions of the intestines were found. There was a large acute splenic tumor and a general acute lymphatic hyperplasia. The cultures from this case examined in twenty-four hours were apparently sterile. Fortunately the cultures were saved. They were left in the thermostat for five or six days, and at the end of that time a growth was observed in the plates from the spleen and liver. The growth proved to be the micrococcus melitensis. When I reported for duty at the First Reserve Hospital I found Dr. Strong ill, with an ill-defined irregular fever. Repeated blood examinations were negative for malaria and typhoid fever. Physical examination was negative but for a general glandular enlargement. As Dr. Strong had been experimenting with his culture of the melitensis recently, my suspicions were aroused, and I tried Widal's test with his blood serum and the micrococcus melitensis. On the sixth day of his fever a positive reaction was obtained in 1 to 100.

Dr. Strong's case proved to be a mild one, accompanied by moderately severe headaches and neuralgia. Within a few days of the beginning of Dr. Strong's illness, a case from the Second Reserve Hospital came to the First Reserve Hospital mortuary for autopsy. I performed the autopsy on this case. Clinically the case (a private of the Twelfth Infantry) presented a history of continued fever for six weeks, not controlled by quinine. At autopsy a general lymphatic acute hyperplasia was found and acute splenic tumor. Spleen weighted over 500 grammes. There were no intestinal lesions. Cultures from blood, spleen, liver and gall-bladder and mesenteric glands were negative for the typhoid bacillus. After three days in incubator cultures from spleen: mesenteric glands and blood showed a faint growth, which proved to be micrococcus melitensis.

I then commenced systematic blood examinations, including Widal's test with micrococcus melitensis, on all cases of continued fever in which blood examinations were negative for typhoid and malaria. I was only able to continue this work for six weeks, but during that time were found the 12 cases referred to above. In all 17 cases have been observed in the Philippine Islands, including 2 autopsies, 1 by Dr. Strong and 1 by myself. These cases were distributed through twelve different regiments, occupying stations in different places in the Island of Luzon.

From this I believe that Malta fever is not an uncommon disease in the Philippines. The name Malta fever is an unfortunate one. Recent reports have shown that Malta fever is not only prevalent in Malta, Gibralta, Corsica and other Mediterranian countries, but cases have been reported by the English Army surgeons, Wright and Smith, from Calcutta and other India stations. One case has been reported by an English Army surgeon which originated in Hong Kong, and several cases have been reported in the United States. One by Assistant-Surgeon Cox, U. S. Army, in an American army officer from Puerto Rico, and 1 case by Musser, of Philadelphia. It would appear that Malta fever is by no means as limited, geographically, as has been thought heretofore. Further investigation of this disease may throw considerable light on a class of continued fevers in the tropics, described by various observers under such names as double fever, relapsing fevers, rheumatic fevers, etc., etc.

THE MALARIAL FEVERS OF THE PHILIPPINES.

In the Philippine Islands, as in all tropical countries, the malarial fevers are widespread. These fevers, as a rule in the Philippines, are not nearly so severe as we were led to expect, after the experience of our troops during the Santiago Campaign in the Spanish-American War. Compared with other tropical countries, the malarial fevers of the Philippines are not severe. While the character of these fevers is generally mild, still there are exceptions to this rule. In some localities malaria assumes a most pernicious character.

In speaking of malarial fevers as comparatively mild, I do not wish to be understood as saying that these fevers are of minor importance in the Philippines. On the contrary, while the malarial fevers here are directly the cause of but relatively few deaths, they are, by reason of the debility and anemia caused by them, a very serious factor in the production of disease in these Islands. It is impossible to estimate how much sickness and debility among the troops malarial fever has helped to produce.

These fevers in the tropics are so widespread that the majority of people sooner or later become infected by the malarial parasite. In tropical countries we have every condition favorable for the development of the malarial parasite outside of and in the human body, as well as the constant presence and activity of the common (if not the only) disseminating agent of the parasite, the mosquito. In addition to the constant presence of the malarial parasites, and the malarial-conveying mosquitoes (the anopheles), the depressing influence of the tropical climate lessens the individual's normal resisting powers, and thereby prepares a favorable soil for the invasion by the parasites. One attack of malarial fever predisposes to another. After the primary invasion by the malarial parasites, a considerable length of time may elapse, even after active symptoms of the disease have subsided, before the individual is free the danger of a recurrence. The parasites remain dormant in the viscera, often for a long time, and are called into activity again and again by any cause lessening the individual's power of resistance. This cause may be either the prodromal or the convalescent period of some acute disease, during some chronic disease, or it may be a slight temporary disturbance due to fatigue, or exposure to the sun or rain.

Thus it is that malarial fever very often complicates other diseases in the tropics. In our investigations we found it complicating surgical cases (such as gunshot wounds, fractures, appendicitis, etc.), and also nearly every acute and chronic disease. As a rule, malarial fever, in the course of other acute diseases, occurs during their convalescence. In typhoid fever, for instance, malarial parasites rarely are active save after convalescence has been established, and the temperature normal for some days. Occasionally malarial attacks appear early in some acute disease or in the prodromal period. It is rare to find the parasites when once the acute disease is fairly established, until after the convalescence begins.

Prevalence.— The malarial fevers were responsible for a larger number of admissions to the First Reserve Hospital than any other one disease. Out of a total of little more than 20,000 medical cases, 4,643 or 23% were diagnosed malarial fever.

Geographical distribution.— In consequence of the above-mentioned favorable conditions common to all tropical countries, the malarial fevers occur to a greater or less extent throughout the entire group of the Philippine Islands. Some of the smaller islands have been reported as being free from malaria and in some of the stations in the southern islands, occupied by our troops, it has been asserted that malarial fevers are absent. On the other hand, scattered through Luzon and the southern islands, severe malaria exists in localities. Often these districts are limited to small areas, a few miles outside of which malaria is mild in character and comparatively infrequent. Severe malaria exists on the Island of Luzon in the Laguna de Bay district and in a number of districts in the north and south. Similar areas also exist in the Island of Cebu. In the city of Manila the type is not severe.

Types of the Philippine malarial fevers.— The types met with were the same as are found in other tropical countries, namely, the estivo-autumnal, the tertian and the quartan. There was this important *difference* from other tropical countries, however, which explains in part the comparative mildness of the Philippine malarial fevers. The predominating type of malarial fevers reported in other tropical countries is the estivo-autumnal. In fact, the term "tropical malaria" is generally understood as meaning estivo-autumnal fever. While tertian fever has been observed as a common type in the tropics, still it has been reported as usually occurring in connection with the estivo-autumnal variety, and has not been found nearly so frequently as the last named.

In the Philippines a much larger percentage of the malarial fevers appears to be due to the tertian parasites than has been reported by investigation in the other tropical countries. In 223 cases of malarial fever in which the parasites were found in the blood, in cases observed in the First Reserve Hospital, Manila, P. I., there occurred the estivo-autumnal parasites in 166, the tertian in 53, the quartan in 1, and the tertian and estivo-autumnal combined in 3.

Taking the pure infections (220 cases) alone, the tertian parasite occurred in 53 out of 220 or 24%, the quartan in less than one-half of 1%, and the estivo-autumnal in 75%. These figures are only the apparent percentages of the frequency with which these various types occur. The great majority of the soldiers admitted to the military hospitals for malaria came in saturated with quinine. It was the usual custom in such cases, diagnosed malaria on admission (who had fever), to administer quinine immediately. In the face of this it can be readily seen how difficult it would be to find the parasite in the peripheral blood in cases of tertian fever. On the other hand, the crescents and ovoid bodies of the estivo-autumnal fevers are little affected by quinine and are easily found.

Out of the 1,187 examinations of the blood made at the First Reserve Hospital in cases diagnosed as malarial fever in but 223 malarial parasites found, all the rest (964) were negative. Of course many of these 964 were not malarial fever, but it is more than probable that a large number of these cases were infections by the tertian malarial parasites. The clinical history of many of these cases

was that of tertian or double tertion infection. This view of the frequency of the occurrence of the tertian malarial fever seems to be borne out by the results of the post-mortem examinations at the First Reserve Hospital.

Out of the 240 autopsies on medical cases at the First Reserve Hospital, an acute malarial spleen and other evidences of malarial fever occurred in 17. (In each of these 17 cases, the malarial parasites were found, post mortem, in coverslip preparations made from the splenic pulp.) Of these 17 cases, 8 occurred in conjunction with other diseases, and in 9 death was due to malarial fever and the pathological condition resulting from the malarial infection alone. Of the 9 cases of pure infection, 4 were due to the tertian parasites and 5 to the estivo-autumnal parasites. When it is remembered that the estivo-autumnal infections are usually far more fatal than the infection by the tertian parasite it would seem from this that tertian malarial fevers must occur in a large percentage of the cases. In fact we may be justified in supposing from this evidence that tertian malarial fever is fully as common as the estivo-autumnal variety in the Philippines.

Reports from the Army medical officers, received from stations throughout the Islands, of the mild character of the malarial fevers and its ready yielding to quinine, would seem to confirm this opinion as to the relative frequency of the tertian variety. As to the morphological and biological characteristics of the parasites of the Philippine forms, no essential differences were noted as compared with those observed by myself in the United States in soldiers at Fort Myer, Va., Savannah, Ga., and from Cuba.

The parasites were the same as those described by observers all over the world, and the clinical course of these fevers did not differ from the descriptions of the same fevers as given by such writers as Machiafava and Bignami of Italy, by Manson of England, and by Thayer of the United States. The estivo-autumnal malarial fever, while occurring generally, was more prevalent in certain commands. This type was especially common in the troops stationed in the Laguna de Bay District, and at the Deposito (Manila Water Resovoir). Tertian malarial fever occurred generally among the troops. It appeared to be the common type of Manila City.

Quartan malarial fever.— But 1 case was observed in a soldier, a private of "E" company, Forty-seventh Volunteer Infantry. This case was one of single quartan fever, and the typical quartan parasites were found in the blood, including the segmenting organisms. The fever was not severe, and was controlled quickly by quinine.

Concurrent or combined infections.— As mentioned before, malarial fever occurs very frequently in the course of other diseases, generally during the convalescent period of those diseases, occasionally in the prodromal stage or in the early stage of some acute disease.

Malarial fever and dysentery.— Out of the 157 cases of chronic and subacute dysentery in which blood examinations were made, the malarial parasites were found in 36, or in nearly 23%. The malarial parasites were found once in the course of an acute dysentery.

Malarial fevers and typhoid fever.— Out of the 125 cases of typhoid fever in which diagnosis of typhoid fever was confirmed by Widal's test, in 5 (or 4%) malarial parasites were found, in each case during convalescent period of typhoid fever.

Malarial fevers and other diseases.— Other diseases, in the course of which malarial fever also commonly occurred, were pulmonary tuberculosis and otitis media. The malarial fevers also frequently occured in surgical cases and in venereal cases.

The mosquito in its relation to malaria.— Unfortunately, before this subject could be studied, I was obliged to return to the United States. But little of my time could be devoted to this most important work. Practically all of it was taken with my duties at the First Reserve Hospital and on the Board of Health. Mosquitoes are very thick and extremely active in the Philippines. It is essential, for a night's rest, to sleep under the cover of a fine-meshed netting. In certain districts, as about the Laguna de Bay in Luzon, mosquitoes are very abundant. I have observed the anopheles in Manila, and at Multinlupa and Pasig on the Laguna de Bay in Luzon. They are extremely plentiful in these latter districts where the malarial fevers are also very common.

UNDETERMINED TROPICAL FEVERS.

There are many fevers occuring in the tropics which are obscure as to their origin. Attempt has been made by several investigators to classify them from a clinical basis, but this is far from satisfactory. This classification on symptoms is not scientific and does not assist to the rational application of hygienic and therapeutic measures. Very little has been done in the tropics in the line of systematic scientific examinations, and the recording of the same in connection with the clinical phenomena. Until systematic laboratory examinations have been conducted for some time, and careful clinical observations made, this class of fevers will remain obscure.

A beginning has already been made by the U. S. Army medical officers, constituting the board to investigate the diseases of the Philippines, and it is hoped that the same work will soon be extended all over the Islands. Every general hospital is equipped with a microscope and other necessary apparatus for the making of blood and other laboratory examinations. When the conditions in the Islands assume a peace basis, valuable work can be done toward the identification of many of these fevers. Some of these obscure fevers are of short duration, while others are of long duration, and the fever is more or less of the continued type. Some assume the relapsing type. The possibility of many of the fevers of long duration being Malta fever, has been noted above. This fever (Malta) appears to be spread widely in

tropical, sub-tropical and temperate zones. The fever described by Munson as "double continued fever," occurring in China, corresponds very closely with Malta fever.

"*Hepatic*" *fever.*— Many of the short fevers have been described as due to climate, to exposure, sun, etc., etc. There is a class of fevers distinct from this latter class which is accompanied, usually, by marked jaundice and acute enlargement of the liver. In these fevers there is pain over liver, and considerable gastroduodenal disturbance. This type of "hepatic fever" occurs most frequently in Europeans and Americans, generally in the first year of their stay in the tropics. These fevers vary in duration and intensity. They last from a few days, to weeks. In fatal cases the autopsy shows marked acute hyperplasia and hyperemia of liver. In 1 case (an American clerk in the quartermaster's department) there were multiple abscesses of the liver without any previous dysentery. This man had been in the Islands about a year. He had had several attacks of jaundice and "indigestion" before the fatal attack. He had a fever of a continued character, not influenced by quinine, for several weeks before death. Blood examinations were repeated frequently, and were always negative for the malarial parasites and for typhoid fever, and there was a persistent marked leucocytosis. Clinically there were marked jaundice, greatly enlarged painful liver, considerable gastroduodenal disturbances and no diarrhea. Autopsy showed greatly enlarged liver, weight 4,470 grammes, filled with many large and small abscesses. Examinations of abscess contents, which were bile stained, were negative for amebæ, and the large intestine showed no evidence of either recent or old dysentery. This case appeared to be one of acute hepatitis, which had gone on to abscess formation and apparently not dependant on a previous dysentery. There was an acute duodenitis, and the liver infection may have come through the bile ducts.

Medical Progress.

REPORT ON PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

(Continued from No. 18, p. 431.)

TETANUS.

Moschcowitz,[5] in a paper which he read at the meeting of the New York County Medical Society, April 23, 1900, summarizes his views as follows:

(1) All forms of tetanus are caused by the bacillus of Nicolaier; hence the diagnosis of rheumatic or idiopathic should have no room in our nosology.

(2) The tetanus toxins appear to have a distinct affinity for the anterior horns of the spinal cord, which may be distinctly recognized by Nissl's method of staining.

[5] Annals of Surgery, October, 1900, p. 575.

(3) The cerebrospinal fluid of tetanus patients is more toxic than the blood.

(4) The antitoxin therapy appears to have a distinct beneficial influence upon the course of tetanus.

(5) With the antitoxin treatment the mortality percentage has been reduced from about 90% to 40%.

(6) Although the use of the serum is a most important factor in the treatment of tetanus, the other recognized therapeutic measures should not be neglected.

TECHNIQUE AND RESULTS OF SUBARACHNOID; COCAINE ANESTHESIA.

Tuffier[6] has performed 63 operations on the perineum, rectum, abdomen, urogenital organs and inferior members, including vaginal hysterectomy, nephrectomy, excision of the rectum, etc., with anesthesia that was induced, exclusively, by a fresh, sterile, 2% solution of cocaine injected into the subarachnoid space at the fifth lumbar vertebra, on a line level with the margin of the iliac crests. In four to ten minutes the patient feels a prickling, tingling and numbness in the feet and legs, and then the operation can be commenced at once, as sensibility to pain and heat is abolished, although sensibility to contact is retained. The analgesia is complete, absolute, and may extend to the axillæ. In one case the patient lifted the stump after amputation of the thigh, to facilitate ligating the vessels. Another listened to the sawing of his femur, but remarked that he could not tell whether it was his leg or the leg of the table that was being sawed. Another, after her kidney had been removed, inquired when the operation was going to begin. Very few consent to be blindfolded. This analgesia lasts from sixty to ninety minutes. The position does not affect the sensibility. No serious accidents have occurred; there was merely a sensation of oppression in the epigastrium, a little nausea and vomiting, sometimes at the time of the injection, but usually not until after a few hours, then it is slight, and yields at once to the ingestion of ice. These accidents were noted 50 times in the 63 operations. Cephalgia was more frequent, but was merely a slight heaviness in the head in two-thirds of the cases. In a few it was more severe and kept the patient awake all night, lasting for forty-eight hours. Sweat, dilation of the pupils, tremor of the limbs and acceleration of the pulse were also occasionally noted; but all without the slightest gravity, vanishing within an hour. The temperature also rose in 15 cases, without operative complications; in 1° to 40° C., but returned to normal by the next day, and in 4 a chill for a few minutes was also noted. The patients were between twelve and sixty-nine years of age, and 39 were men. Tuffier uses a special platinum needle, straight, 9 centimetres long, the external diameter 11 millimetres, and the lumen 8 millimetres. It is strong, so that it will not break if it comes in contact

[6] Semaine Medical, May 10, 1900; Journal of the American Medical Association, June 9, 1900, p. 1483.

with the bone, and the tip is very short. The dose should not exceed .015 mg. of cocaine. The technique is much the same as for lumbar puncture. The needle is inserted about 1 centimetre from the median line of the spine, with the left forefinger on the apophysis as a guide. There is scarcely any resistance to the passage of the needle, and the issue of a few drops of cerebro-spinal fluid is the sign that the needle is in the right place. The patient should be warned that he is about to feel a prick and not to stir. Children and hysterics are liable to be afraid, and Tuffier rejects the method for them on this account. In case the anesthesia fails for any reason, the injection does not counter-indicate resorting to general anesthesia at once. He changed to ether several times in his early experience, noting merely in such cases that the usual period of agitation was diminished.

EUCAINE IN SPINAL ANESTHESIA.

Englemann,[7] of Bonn, reports his experience with eucaine bacilli. He states that after the injection of .01 through a lumbar puncture very unpleasant after-effects were observed, without more than a slight para-esthesia resulting. That one-half hour after the injection, sacral pain appeared, which gradually became quite severe. Also nausea, vomiting, chill, fever to almost 30° C., headache, diminution and irregularity of the pulse, dyspnœa, and precordial distress. After a dose of morphia the symptoms disappeared with an attack of sweating, except the violent sacral and head pain, which lasted for several days and forced him to remain in bed. The injection was a personal experiment, and the writer advises against further experiments with eucaine bacilli.

SPINAL ANESTHESIA.

A. Bier[8] has contributed some observations of this method, including some personal ones. He has noted that unpleasant symptoms (vomiting, headache, weakness, vertigo) of even day's duration after the injection of very small doses of cocaine into the subdural space. He states that collapse, sensations of oppression, chills, fever and even 1 death, have occurred in the experience of other surgeons, especially the French. He advises against the method as at present used, and especially against the use of doses exceeding 15 mgs.

MEDIAN OSTEOTOMY OF THE HYOID BONE AS A METHOD OF PERFORMING PHARYNGOTOMY.

Valls[9] proposes this new operation in order to overcome some of the dangers and difficulties that surround the removal of malignant or benign growths from the pharynx or the base of the tongue, and that are met with in the complete removal of the tongue.

The method of operating is as follows: An incision in the median line is carried from the mental symphysis to the thyroid cartilage. The skin and subcutaneous tissue can be incised at one cut. The bleeding is insignificant. The next step is the denudation of the hyoid bone in the median line. The superficial cervical aponeurosis is incised, the myohyoid muscle is raised in the median line by using the grooved director, so that its upper border can be severed from the hyoid bone in the median line. Here an arteriole or two may be met. The hyoid bone is then resected in the median line with the bone forceps; the two parts of the myohyoid can then be gradually separated with it, thus providing an opening about an inch and a half wide.

Two ways are open to the surgeon: Below is the thyrohyoid membrane; above the mucous membrane alone separates him from the pharynx. The closure of this wound is very simple after the operation has been completed. It is not necessary to attempt an osseous suture. The result is functionally as good if the muscle and fibrous tissues are sutured. The result in fibrous union is just as efficient from the functional standpoint.

A preliminary tracheotomy has not been found essential to successful operating when this incision is employed, except where the operation involves the larynx directly.

The superior route is to be employed in total removal of the tongue or removal of tumors from its base, while the other route is best for attacking tumors of the pharynx, especially of the epiglottis, and foreign bodies.

The author formulates the following conclusions:

(1) The median osteotomy of the hyoid bone is a simple, easy operation and essentially benign.

(2) It permits the penetration into the pharynx and gives a better view and operative field than does Malgaigne's superhyoid operation. Foreign bodies, enucleable tumors, cancers limited to the epiglottis, and especially grave syphilitic lesions, are its indications.

(3) It facilitates the removal of intramuscular tumors at the base of the tongue, lipomas and hyoid cysts which are difficult to remove by the lateral route.

(4) It facilitates the total amputation of the tongue in cases where the cancer is situated in the base. The amputation is complete, and is less dangerous by this method.

(5) There are no remote sequelæ from the osteotomy. It leaves no deformity behind it or functional disability.

RADICAL OPERATION FOR DIVERTICULA OF THE ESOPHAGUS.

Dr. F. Veiel[10] (Tübingen) reports and analyzes 22 cases of radical cure of this unusual lesion. The symptoms, as illustrated by a case, were a smacking noise during deglutition, progressive interference with deglutition. A bulging at the anterior border of the sterno mastoid muscle during rapid drinking. Eructation of food or liquids after violent coughing or on bending forward. The but-

[10] Beitr. zur klin. Chir., Bd. xxvii Schluss, H. 3.

ton of an esophageal sound passed into the pouch can be felt in the neck.

The diverticulum is exposed by an incision as for esophagotomy at the site of the swelling. It is isolated, ligated and excised. The wound is generally drained, sometimes not. Food by mouth on the fifth day.

Kocher advocates a transverse incision, but the vertical one is generally used. Failure appears to be due to lack of care in suturing the esophagus wound and in feeding by mouth too early. There were 5 deaths in 22 cases.

Invagination of the sac has been done with good results.

THE SURGICAL TREATMENT OF PULMONARY GANGRENE.

Em. Herczel, of Budapest, in an interesting article gives a good résumé of the technique of pneumotomie. He avoids exploratory puncture, which he considers liable to infect the pleural cavity in case the parietal and visceral pleuræ have not become adherent, liable to infect healthy lung tissue when the needle is withdrawn, and liable to cause severe hemorrhage from puncture of large vessels. He does not practise it unless to be followed by pneumotomie, in which case the needle is used as a guide to the cavity to be opened.

The resection of the ribs should be free. He claims that the more extensively the lung is exposed the easier does the examination in manipulation of the lung become, and the more rapid will the cavity close and heal. One to two ribs are removed in the usual manner. Should three to four ribs be resected a flap incision of the superjacent soft parts is the most satisfactory method.

After the resection, if the pleural surfaces are adherent, the operation becomes easier and safer. The retraction of the intercostal space on deep inspiration, and the slight descent of the lower lung border noted before the operation, the writer thinks, would indicate this. Sometimes after the resection of the ribs, the lung can be seen to slide up and down during respiration, as the intestine is seen through the unopened peritoneum. When adherent, the parietal pleura appears, grayish yellow spotted with fat, thickened and dense to touch. Finally, a fine needle pushed into the lung remains stationary if the lung is adherent, and consequently fixed to the chest wall. A free lung would cause it to oscillate. The "Shapiciko" and "Tuffier" methods are also here mentioned.

The attempts to produce this adhesion of the pleural surfaces by ignipuncture, electrolysis, cauterization, chloride of zinc and other methods have now been abandoned in favor of immediate union by suture. This, it is claimed, can be easily done by experienced operators, especially when the surface of the lung is exposed, and if it is forced into the wound by inspiration or coughing. The lung once fastened to the edges of the wound, its collapse or pneumothorax is avoided. The operation can now also be quickly finished.

As regards the pneumotomie in indurated infiltrated, anemic tissues, when the blood circulation is impeded, the lung can be satisfactorily opened with the scalpel, but since eventually the operator meets soft, healthy tissue and is dealing with foul gangrenous tissue in order to limit infection, the use of the Paquelin cautery is to be preferred.

The writer considers that an anesthetic is hardly necessary. He would not use ether. In an operation recorded, chloroform was used.

In regard to the results of operative treatment, Herczel claims to show that in 91 cases there was recovery in 60 or 61%.

RESECTION OF GASTRIC CARCINOMA.

An improvement in the technique of this operation has been devised by W. G. MacDonald,[11] by which the time required for the operation is shortened, and the difficulties of pyloric resection diminished. For full details a perusal of the original article is recommended. The procedure, in brief, consists of a resection of the stomach proximally, and below the pylorus to the extent indicated by the disease. The resected stomach is sutured. The resected duodenum is sutured. A lateral anastomosis is made between the duodenum low down and the jejunum to allow the bile to flow into the latter. A lateral anastomosis is also made between the stomach and the loop of the jejunum formed by the duodeno-jejunal anastomosis. This avoids a discharge of bile into the stomach.

PERFORATING DUODENAL ULCERS.

Weir,[12] says of this affection that it is much more rare than the ulcer of the stomach; is much more difficult to diagnosticate properly, and is more apt to be confounded with other more distant surgical lesions, such as appendicitis, etc.

The following contrasting symptoms have been grouped as an aid to this differential diagnosis:

Gastric ulcer. — (1) More frequent in women — twenty-fifth to fiftieth year; (2) pain promptly after eating; (3) pains relieved by vomiting; (4) frequent biliary, mucous and food vomiting; (5) marked dyspeptic symptoms; (6) frequent bloody vomiting; (7) more seldom bloody stools.

Duodenal ulcer. — (1) Occurs more frequently in males; (2) pain in right hypochondrium or to the right of the parasternal line; (3) comes on one or two hours after meals; (4) no relief by vomiting, latter not frequent; (5) bloody stools (melena or bright blood) more common than bloody vomiting; (6) jaundice, if present, would contribute to the diagnosis.

The usual symptoms of perforation are the following: Great pain is usually felt at the epigastrium or to the right of this region, as was noted 26 times in the author's 47 cases. It has a few times been observed at the umbilicus and in the left side; but in 23 others of the 47 instances it was simply recorded as abdominal pain. Vomiting often follows the attack of pain. It occurred

[11] Annals of Surgery, vol. xxxiii, p. 157, 1901.
[12] Medical Record, May 5, 1900; American Journal of the Medical Sciences, August, 1900.

in 28 out of the 34 instances. Shock is not often met with, but may be severe and fatal. Peritoneal symptoms rapidly develop, with a tendency in some cases to be localized in the upper part of the abdominal cavity and in the right side; when these signs show themselves mostly to the right and at or below the level of the umbilicus, an appendicitis is necessarily simulated. When the liver dulness has disappeared nearly up to the mammary line, air extravasation may be suspected, and when it is present it will aid in establishing a diagnosis. This symptom of loss of liver resonance, unless marked, is so often found to be due to a distended colon, that it should not be much relied on.

In considering the diagnosis of perforated duodenal ulcer as just given, the author feels that more weight and attention should be given, (1) to the previous history, which shows, contrary to the opinions of many anterior observers, that in the 51 collected cases of operation for the relief of such conditions, there was a history of gastric or dyspeptic symptoms given in 25 out of the 34 instances in which this point was noted; (2) the fact that the initial or early pain was developed in 26 instances out of 47 in the epigastrium is also important; and in the right hypochondrium 13 times. The third actor of value in the diagnosis as well as the treatment of the symptoms of perforation peritonitis, whether from stomach, duodenum, gall bladder, appendix or any other part of the intestinal tract, is the prompt resort to an exploratory incision. This need of an early determination of the site of the perforation has been shown frequently. The mortality in these cases clearly depended on whether the patient underwent surgical intervention within twenty-four hours from the inception of the perforation.

The results in the 51 cases reported bear out this conclusion. There were 25 cases in which the lesion was recognized and closed at the time of operation; of these 13 underwent operation after thirty hours' delay, and all resulted fatally; 12 other patients were operated on within that time, and 8 survived, giving thus only 33⅓% of mortality. The mortality was formerly 60%. Thus there has been great improvement in the past five years. Before that time, in 70% of the cases operated on for duodenal ulcer, it was not found; it was found and sutured in 25%. In only 2 cases, or 10% was the possibility of a duodenal perforation considered. Contrast this with the 31 cases operated on since 1895, when the analogous surgery of gastric ulcer began to develop. Of these 31 cases the perforation was not found in only 11%. It was found and sutured in 26 cases, or 65%. Its presence was considered in diagnosis in 11 cases, or 35%.

(To be continued.)

A DIMINUTIVE MOTHER.—Mrs. John Petty, who recently died at Yaphank, Long Island, N. Y., at the age of thirty-seven, was the mother of twelve children, although only two and one-half feet in height.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

HENRY F. HEWES, M.D., SECRETARY.

REGULAR meeting Wednesday, February 20, 1901, DR. V. Y. BOWDITCH in the chair.

DR. C. F. WITHINGTON read a paper entitled

EXPERIENCE WITH THE WIDAL REACTION IN TYPHOID FEVER.[1]

DR. GEO. B. SHATTUCK presented a paper on

THE WIDAL REACTION IN TYPHOID FEVER.[2]

DR. MASON: I am impressed every week with the value of this test, certainly in hospital practice. I have here two charts which Dr. Thayer has prepared, showing the same fact that Dr. Withington and Dr. Shattuck have dwelt upon, that in exceptional cases a great number of tests fail to show the reaction. In one recent case many tests were made with no positive result, and the symptoms, which are marked on the chart, correspond with those of typhoid, as did the appearance of the patient and the course of the disease. I think one of these cases was mentioned by Dr. Withington, a patient who had venous thrombosis, but the other one is quite recent and not included in his series. Absence of rose spots, I see, is noted in both these cases, but rose spots may escape notice, as in a good many cases they are few in number, and such a negative statement is of no great importance in regard to the diagnosis. In one instance I remember a patient who went through a long typhoid and had no Widal reaction during the primary attack, but during a relapse the reaction was present. Perhaps that may be not uncommon, but I did not observe whether Dr. Withington mentioned it, whether the Widal test may be positive during relapse in any considerable number of cases in which it has not appeared in the primary attack.

DR. J. L. MORSE: A few months ago I had to look up the serum reaction in infancy, and at that time found out a few points which to me, at any rate, were rather new. In the first place, the serum reaction evidently occurs in infantile as in adult typhoid and under the same conditions. There seems to be no data with regard to the serum reaction in fetal typhoid, because if the child is born without the reaction it is not certain that it has not had typhoid; on the other hand, if the child is born dead with the reaction it is impossible to tell whether the reaction is the result of typhoid in the fetus or has been transmitted from the mother. In children born alive and well of women with typhoid or convalescent from typhoid the serum reaction may or may not be present. If the serum reaction is present it is probably due to transmission from the mother through the placenta and not to fetal typhoid, because as far as

[1] See page 442 of the Journal.
[2] See page 443 of the Journal.

we know typhoid in fetal life is always fatal. The strength of the serum reaction in the infant is always less than that in the mother. This weakness is probably due to its transmission through the placenta, the placenta acting as a filter. The transmission of the agglutinating power apparently depends on two factors: the strength of the agglutinating power in the maternal blood and the length of exposure. This has been determined by experiments on animals. Nursing mothers with typhoid at times present the serum reaction in the milk, at other times they do not. The strength of the serum reaction in the milk is always less than that in the maternal blood, and that in the child's blood is always less than that in the milk. It has been found that this serum reaction may appear within twenty-four hours after beginning to take the milk, and never lasted more than a week after ceasing to take the milk. If the child takes the milk again it reappears in twenty-four hours or so. The reason that the strength of the reaction in the milk is less than that in the mother's blood is due, (1) to the resistance met in traversing the mammary gland and (2) to some unknown condition of the child's digestive tract.

Dr. Mason: In the absence of this test sometimes the diazo urinary reaction is of value. Although not a positive test of typhoid, it is confirmatory.

Dr. Withington: In some of the cases of jaundice without apparent typhoid, it is possible that the patient has had typhoid fever and an infection of the gall bladder with the typhoid bacillus which is a recognized fact in typhoid fever, and, unless there was positive evidence from the autopsy that the patient did not have typhoid fever, it would be certainly a possible supposition to make that the individual might have had typhoid fever with gall bladder infection which produced the jaundice, and, so far as the clinical history was concerned, produced nothing else but the jaundice.

Dr. Charles Harrington read a paper entitled:

SOME REPORTED CASES OF TYPHOID FEVER ATTRIBUTED TO CONTAMINATED OYSTERS, WITH CERTAIN FACTS CONCERNING THIS MEANS OF INFECTION.[3]

Dr. Barnes: I was very glad to listen to the paper of Dr. Harrington, because last year or the year before, a paper was read before the American Public Health Association by a gentleman from Baltimore, rather discrediting the possibility of contaminating oysters by sewage of that city, and after I read the paper, I received a report of the sewage commission of Baltimore, recommending the discharge of Baltimore sewage into the Chesapeake. The question was debated as to the possibility of contaminating the oyster beds, the contention being that the proposed point of sewage discharge was too remote to cause any injury to the beds. As a matter of precaution, however, a law prohibiting the taking of oysters within a radius of 4 miles of the out-fall was suggested. With an enormous volume of sewage and a very slight tidal flow, it seems to me doubtful if the proposed law would insure the safety of the plan proposed, and that the largest source of oyster supply of the United States may be very seriously injured from suspicion merely of the origin of a case of typhoid. It is therefore to be hoped Dr. Harrington's paper may be brought to the notice of citizens of Baltimore. In the report there was an alternate plan for the soil treatment of the sewage of the city, which, from European experience and the success which has attended this method of disposal in sixteen cities and towns of Massachusetts, ample assurance is given of freedom from objectionable features when this treatment is employed.

Dr. Mason: I have been very much interested in Dr. Harrington's paper, and am somewhat familiar with the literature of the subject through the Connecticut Board of Health and the Local Government Reports. This has become a practical question, both to the oyster dealer and to the general public. I must confess that I have not yet reached the point where I can advise persons who ask me with regard to it to abstain from the use of raw oysters. I do not believe there is so much danger as the public may infer from a few isolated epidemics; therefore, in my opinion physicians should be somewhat cautious in adding to any nervousness that may already exist. The raw oyster has almost disappeared from the dinner table. A lady said to me the other day that she had eaten oysters three weeks before, and wanted to know if she was out of danger. I told her I thought the time was up.

Dr. E. N. Whittier read a paper entitled

MEANS OF INFECTION IN TYPHOID FEVER.[4]

Dr. Richardson: It might be interesting for me to say a few words about the possibilities of the Marion contamination. The beach where the suspected oysters lay is on the western side of a small area of water partly enclosed by two wharves, one of which is my own. The tide has free access to this little bay, which is not more than a hundred yards in diameter. On the other side of my wharf is a sandy beach where I kept oysters all through the month of September. My family used these oysters at nearly every meal during the month of September, and no one suffered in consequence. I have little doubt, however, that all the water in that part of Marion was sufficiently contaminated with sewage to make the oysters dangerous as an article of food.

Dr. Calvin G. Page read a paper on

EARLY DIAGNOSIS OF TYPHOID FEVER BY ISOLATION OF BACILLUS TYPHOSIS FROM STOOLS; CONCLUSIONS OF DR. L. REMY, BASED ON THE USE OF HIS ASPARAGIN–LACTOSE–CARBOL GELATINE.[5]

Recent Literature.

Physical Diagnosis in Obstetrics. A Guide in Antepartum, Partum and Postpartum Examination for the Use of Physicians and Undergraduates. By EDWARD A. AYERS, M.D. Professor of Obstetrics in the New York Polyclinic; Attending Physician to the Mothers' and Babies' Hospital. Pages 283, and 67 illustrations. New York: E. B. Treat & Co. 1901.

The author of this book is the editor of the monthly journal *Obstetrics*, and the volume is a reprint of a series of continued essays published in *Obstetrics*. The writer has constructed a book which will be of much use in the careful study of clinical obstetrics, especially on the subjects of diagnosis, to the advanced student desirous of further knowledge in the subject, to the practitioner anxious to keep abreast of the subject and also to the teacher of clinical obstetrics as a guide in his own work. For the average undergraduate with a limited amount of time and clinical material at his disposal, we believe the book will be of little value, while the man, who at graduation knows the whole subject of obstetrics, will have no use for such a book as this.

The author discusses with considerable detail the various points in diagnosis of the maternal and fetal conditions before, during and after labor, taking up practically every point in the maternal history, the various methods of examination and the conditions in the different stages of labor which may in the case have a bearing upon diagnosis, prophylaxis or labor management. As a basis for the text an elaborate history chart of several pages has been inserted, and the text following is largely an elaboration of the various points in the chart. Almost nothing in the way of treatment is attempted in the book except in a suggestive way. Charts of this nature are undoubtedly too elaborate for the busy general practitioner but if given to the student in perhaps a modified form would be of great value in training his observing powers and in calling his attention to points which are often overlooked.

The book is a contribution of value to obstetrical literature, more from a teaching than a practical standpoint.

A Manual of Practical Hygiene for Students, Physicians and Medical Officers. By CHAS. HARRINGTON, M.D., Assistant Professor of Hygiene in the Medical School of Harvard University. Twelve plates and 105 engravings. Philadelphia and New York: Lea Brothers & Co. 1901.

The author, in his preface, states his object "to provide a students' textbook, which should cover the most important topics included in the wide domain of hygiene, and be useful in the laboratory and as a reference book for practitioners and health officers."

In the first half of the work the author follows quite closely the method of the earlier English writers upon the same subject, treating of food, air, soil and water.

In the opening chapter upon food, the author treats of the subject from the standpoint of many years of experience as a food chemist, both for the State Board of Health and for the city of Boston. His clear and positive manner makes this chapter one of special value to the student and practitioner. It is well illustrated with cuts, and a series of plates showing the starches most commonly employed in food adulteration.

The topics presented in the latter portion of the work are habitations and schools. The portion relating to plumbing is especially full and clearly illustrated. Disposal of sewage and garbage, disinfectants, quarantine, military hygiene, naval and marine hygiene, tropical hygiene, hygiene of occupations, vital statistics, personal hygiene, vaccination and disposal of the dead are also discussed. The author has presented the latest and most modern information upon each subject treated.

We would suggest, however, that in a second edition, the author may present a chapter upon the all-important, in fact, to the practical hygienist, the most important of all questions, the management and control of infectious diseases. The subject is of sufficient value to warrant separate treatment in a chapter by itself, since it comprises fully half of the duties of all officials who have to do with sanitary questions.

Studies in Human and Comparative Pathology. By WOODS HUTCHINSON, A.M., M.D., Professor of Comparative Pathology and Embryology in the University of Buffalo; formerly Professor of Anatomy in the State University of Iowa, U. S. A., and Lecturer on Diseases of Animals in the Medical Graduates' College and Polyclinic, London. Edited by DR. EDWARD BLAKE. London: Henry J. Glaisher. 1901.

This book is essentially a collection of short essays on a great variety of topics connected with the subject of the "Nature of Disease," on which the author brings to bear a good knowledge of zoölogy, embryology and comparative pathology. It contains much information that will be of interest to medical men. It is written in a most pleasing and attractive style, and it shows the author to be a careful thinker and observer. The work deserves a wide circle of readers.

Medico-Surgical Aspect of the Spanish-American War. By LIEUT.-COLONEL DR. NICHOLAS SEHN, Chief Surgeon U. S. Volunteers, etc. Chicago: American Medical Association Press. 1900.

This book is a combination of the "magazine" article of today, and a report of the author's observations and experiences in the late Spanish-American War.

It is like a nut with some "meat," but with an awful thick shell.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 9, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

THE PREVENTIVE TREATMENT OF RABIES.

Statistics are gradually accumulating in sufficient numbers to be of decided value in the final determination of the important question of the possibility of preventing hydrophobia. The disease is not a great menace to man, and no doubt continually increasing vigilance will more and more prevent the inoculation of human beings by rabid animals. The possibility, however, will always remain of the sporadic appearance of the disease, and continued studies as to its prevention and pathology are very much to be desired. A publication from the recently organized department for the Preventive Treatment of Rabies, at the College of Physicians and Surgeons of Baltimore is of very considerable interest in this connection. Judging from the experience at this institution there is small cause for pessimism regarding the result of the Pasteur treatment if properly applied at a sufficiently early period after the original inoculation:

The report before us gives the outcome of the treatment of 209 cases, ranging in age from two to eighty-two years: The wounds were inflicted by dogs in 188 cases, in 13 cases by cats, in 1 by a calf, in 1 by a pet pig. In 6 cases the wounds were not the results of bites. One hundred and forty-seven persons came to receive the treatment during the first week after having been bitten, 27 the second week, 11 the third week, 7 the fourth week, 11 the fifth week, 4 the sixth week and 2 the eighth week. In 3 cases the treatment was discontinued, because the animal, held under observation, was evidently not rabid. Four persons abandoned treatment. One patient six months pregnant was treated without untoward result. There were 5 abscesses in 6,270 injections. There has been but 1 death from any cause. This death was caused by rabies. The history of this case, in brief, was as follows: A lad eight years old, bitten February 2, 1900, was admitted February 4th. He received only one treatment, consisting of two hypodermic injections. He was removed from the institution and treatment discontinued on February 5th against the advice of the physicians. After the inoculated rabbits and a cow bitten by the same dog developed rabies, the child was brought back on February 25th. He developed rabies March 14th and died March 17th. As the report says, a case of this character cannot be attributed to failure of the treatment, but to delay in resorting to treatment.

These are certainly most strikingly favorable results, and seem to point the lesson too often ignored, that promptness in submitting to treatment and faithfulness in carrying it out are of the utmost importance. It is altogether probable that the various failures from time to time reported are due rather to the negligence of the patients than to the suggested inefficiency of the treatment.

An added scientific interest has been given the whole subject of rabies both in man and animals by recent pathological investigations at the hands of Babes, Nélis, Ravenel, McCarthy and others, who have shown, with certain variations in detail, that constant changes occur in the central nervous system of animals in which hydrophobia has run its course. These changes are particularly observable in the dorsal root ganglia of the cord, consisting essentially in a proliferation of fixed cells and a coincident destruction of the nerve cells. Whether this alteration is absolutely peculiar to hydrophobia may, perhaps, be questioned; nevertheless, the finding is so constant that it may very materially aid in the more rapid determination of the diagnosis, than is possible by the inoculation method, and thereby permit an earlier rational treatment of the disease in persons secondarily affected.

In general the work, both on the side of pathological anatomy and of prophylaxis, is progressing most favorably. It is not too much to hope that this much dreaded, if somewhat infrequent disease, may finally be brought under complete control.

THE PREVALENCE OF SMALLPOX.

The past winter has seen an unusual prevalence of smallpox throughout the United States, often occurring sporadically, but at times reaching mild epidemic form. Various reasons may be sought for this state of affairs. No doubt one of the most conspicuous is the general carelessness of the public regarding vaccination. Unless people are frightened by the actual presence of the disease in virulent form, they are exceedingly likely to evade the regulations of boards of health, particularly in those regions where the anti-vaccination fanaticism is rife. Another very great menace to this country is the importation of the disease

from foreign countries. For example, at the port of New York the resources of the quarantine department are at the present time being taxed to the utmost, owing to the unusually large immigration from Italy. Almost every steamer arriving from Naples has brought one or more cases of the disease, and the quarantine station on Hoffman Island has many hundred detained passengers, awaiting the examination of physicians. This constant menace to a city like New York, and secondarily to the country at large, is naturally very great, and it is little to be wondered at that cases occasionally escape the vigilance of the authorities.

In the South, again, the negroes are a prolific cause of the spread of the disease, owing to their avoidance of vaccination and their disregard for the disease itself. It is said that most of the cases which have occurred in Washington have come from the South.

An interesting report comes from Tennessee, quoted from a Nashville paper, showing how much may be done by vigorous measures on the part of the appointed authorities:

From February 13, 1899 to October 1, 1899, there was a total of 1,014 cases of smallpox in Tennessee, of which only 11 proved fatal. From October 1, 1899, to March 5, 1900, there occurred 3,004 cases, with only 46 deaths. From March 5, 1900, to October 1, 1900, 1,389 cases occurred, with 18 deaths. From October 1, 1900, to April 1, 1901, there were 4,207 cases, with 98 deaths. On April 1, 1901, there were 491 cases in the State, 49 counties being infected. At present the disease is to be found in only 28 counties—which shows that 21 counties have been freed from the disease during the past eighteen days. According to these figures, which are official, there have been 10,105 cases of smallpox in Tennessee during the past two years and two months, and 173 deaths as a result of the disease. This is a death rate of only about 1.7 per hundred. It shows the disease to be of the mildest type.

The fact that many cases have been of the mildest type has naturally conduced to a certain sense of security, and hence, no doubt, to greater carelessness in guarding against the disease. This is unfortunate, in so far as it leads to laxness in the enforcement of vaccination, and is, no doubt, one cause of the unusually wide dissemination of the disease. Although sporadic cases may always occur, smallpox, like typhoid fever, must be regarded as a preventable disease, and vigilance should never, for a moment, be relaxed. It is a reasonable expectation that smallpox may, in time, be eradicated, but such a consummation clearly cannot be reached until the people work in complete accord with the health officers, and cease to evade and antagonize the regulations provided for their good.

A CENTENARIAN. — It is reported that Mrs. Rebecca Packard, one hundred and five years old, has died in Covington, Pa.

MEDICAL NOTES.

WESTERN OPHTHALMOLOGIC AND OTO-LARYNGOLOGIC ASSOCIATION. — The following officers were elected at the sixth annual meeting of the Western Ophthalmologic and Oto-Laryngologic Association held in Cincinnati, April 11th and 12th: Dr. C. R. Holmes, Cincinnati, O., President; Dr. W. L. Dayton, Lincoln, Neb., First Vice President; Dr. O. J. Stein, 100 State Street, Chicago, Treasurer; Dr. William L. Ballenger, 100 State Street, Chicago, Secretary. The next meeting will be held in Chicago, April 10, 11 and 12, 1902.

OFFICERS OF ASSOCIATION OF AMERICAN PHYSICIANS. — The following officers of the association were elected May 2, 1901, for the ensuing year: President, James C. Wilson; Vice President, James Stewart; Recorder, S. Solis Cohen; Secretary, Henry Hun; Treasurer, J. Crozier Griffiths; Councillors, Frank Billings, Francis P. Kinnicutt; Representative on Executive Committee of Congress, William Osler; Alternate Representative, Francis H. Williams.

PLAGUE NEAR CONSTANTINOPLE. — A case, officially pronounced to be plague, has occurred in one of the suburbs of Constantinople.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 8, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 74, scarlatina 23, measles 107, typhoid fever 4.

OPPOSITION TO VACCINATION AT HAMPTON, N. H. — A recent order from the State Board of Health, directing the school board to have all children vaccinated, who had not been vaccinated, or who had not had smallpox, has met with considerable opposition. The order is regarded as arbitrary and unnecessary.

TYPHOID FEVER AT NEW HAVEN, CONN. — During the month of April, 37 deaths from typhoid fever occurred in New Haven. Many patients are still critically ill.

NEW YORK.

OPENING OF NEW YORK HOSPITAL FOR THE CARE OF CRIPPLED AND DEFORMED CHILDREN. — The New York State Hospital for the Care of Crippled and Deformed Children, at Tarrytown, will be formally opened Friday, May 17, 1901. The Right Reverend Henry C. Potter; D.D., president of the hospital, will preside. Short addresses will be made by Professor Robert F. Weir, M.D., of Columbia University, Professor A. Alexander Smith, M.D., of the University of the City of New York, and Professor William M. Polk, M.D., of Cornell University. Tickets for a special train

from New York to Tarrytown may be had upon application to Dr. Newton M. Shaffer, 28 East 38th Street, New York.

Closing of Pathological Institute of the New York State Hospitals. — The work of the Pathological Institute of the New York State Hospitals has come to an untimely end. As a result of action by the legislature, removing Director Ira Van Gieson and depriving the Institute of quarters and funds for maintenance, the entire medical staff has resigned. Dr. Van Gieson, it is stated, has applied to the Supreme Court for an injunction restraining the State Commission in Lunacy from interfering with specimens and other property of the Institute.

Edward N. Gibbs Memorial Prize Fund. — The trustees of the New York Academy of Medicine announce the receipt of $10,000 from Mrs. Sarah Barker Gibbs and Miss George Barker Gibbs, for the establishment of the Edward N. Gibbs Memorial Prize Fund, the income to be awarded, triennially, to the physician, of regular standing in the medical profession of the United States of America, who shall present the best original essay upon the etiology pathology and treatment of the diseases of the kidney.

A Family of Simulators.—The champion family of frauds has been discovered. A boy of thirteen, who feigned blindness, was found on the streets appealing for charity, and when a detective visited the home of his parents, which was a very comfortable one, the mother was seized with such a terrible fit of coughing (got up for the occasion) that she could not answer any questions, while his step-father showed a frightful-looking "cancer" of the leg which proved to be ingeniously constructed of painted putty.

Bequests to Hospitals. — By the will of Joel Goldenberg, a wealthy merchant, the greater part of his estate, believed to exceed $1,000,000, is left to the Mount Sinai Hospital. There are specific bequests of from $1,000 to $5,000 to fourteen charitable institutions, among which is included the Montefiore Hospital for Chronic Diseases, and, in addition, the Training School for Nurses of Mount Sinai Hospital receives $5,000.

Miscellany.

RECEPTION HOSPITALS FOR THE INSANE.

In the eighth annual report of the State Charities Aid Association to the State Commission in Lunacy, just issued, the recommendation is made that small reception hospitals be established in New York and other cities. There are now more than 22,000 dependent insane patients in the State, and statistics show that the yearly increase of the insane is out of proportion to the increase in population. It is believed that many of the now hopeless cases might be saved if the patients could have the benefit of the best medical skill, such as is now given gratuitously by the most distinguished members of the profession to those suffering from other forms of disease in the general hospitals of every city in the State. It is suggested that the proposed psycopathic hospitals should be made branches of the existing State institutions and be governed by the same managing boards. "Into the Reception Hospitals for New York City," the report goes on to say, "(a branch of the Manhattan State Hospital and taking the place of the wards for the insane at Bellevue), would be gathered all recent cases of the committed insane; and here they should be examined and classified by the attending physicians before being treated either within the wards of the hospital or elsewhere. Cases possibly curable would doubtless be kept for a limited period in the reception hospital under the daily care and constant advice of the most eminent members of the profession, until it was thought best to send them on to the main hospital. The hospital should receive not only the destitute, but those able to pay for themselves, that all may receive the benefit of the best neurological and alienist skill that New York City can provide. It is also desirable that the reception hospital should open its doors for clinical teaching. It is under the roof of the New York reception hospital that the already established pathological institute would naturally find its home."

Obituary.

ROBERT WILLARD GREENLEAF, M.D.

Dr. Robert Willard Greenleaf, of Boston, died suddenly April 28, 1901, at the age of forty-six. He was born in Charlestown and had always lived within sight of the State House. He graduated from Harvard in 1877 and became an assistant in botany under Prof. G. L. Goodale. He entered the Harvard Medical School in the fall of 1881, receiving the degree of doctor of medicine in 1885. He joined the Massachusetts Medical Society in 1884, while serving a term as house officer at the Boston City Hospital. He was an assistant in the office of the superintendent of the hospital for a short time after his term of service as house officer ended, and then entered upon the practice of medicine, with an office at 561 Boylston St., Boston, where he lived the rest of his life. Soon after he became an instructor in histology at the Harvard Medical School. He taught botany in many of the private schools and lectured upon that subject to the graduates of the Boston Normal School. He was also professor of materia medica and botany at the Massachusetts College of Pharmacy, a position he held at the time of his death. He was an examiner of the Penn Mutual Life Insurance Company.

He was appointed a district physician of the Boston Dispensary and served for several years, resigning to accept a position as physician. In 1900 he was elected president of the staff. He was the author of the Centennial Report of the Dispensary, a valuable and interesting paper. He had a large private practice, but was not prevented, thereby, from giving freely of his time and experience to the poor and needy.

Dr. Greenleaf was an energetic, conscientious, able physician, generous to every one except himself, affable, tactful, sympathetic. By his death the medical profession, and, indeed, the whole community, has suffered a great loss.

RESOLUTIONS ON THE DEATH OF ROBERT WILLARD GREENLEAF, M.D.

At a special meeting of the staff of the Boston Dispensary, held April 30, 1901, the following resolutions were adopted, and it was voted to send a copy of them to the *Boston Medical and Surgical Journal*.

Dr. Robert Willard Greenleaf, our friend and co-worker, died suddenly, Sunday, April 28th.

We, the members of the staff of the Boston Dispensary, desire to place on record our appreciation of him as a man and physician.

We testify to his loyalty to his friends, his devotion to his profession, and the loving tenderness and watchful care for his patients.

His earnest endeavors in behalf of this institution will be an incentive for more active work on our part.

Our profession has lost an able member, and we a loyal and true friend.

We extend to his mother and sisters our deepest sympathy.

WARREN F. GRAY,
Secretary of the Staff.

At a special meeting of the executive committee of the Boston Polyclinic the following action was taken:

It is with deep regret that the executive committee of the Boston Polyclinic meets to express its sorrow over the loss of our fellow-worker, Dr. Robert W. Greenleaf.

No young man has worked harder to broaden the field of education or shown more marked devotion to every duty — always willing to give his time and skill for the alleviation of poverty and suffering wherever found.

We wish to express to his family our appreciation of him as a man — respected by associates and most beloved by patients.

It was voted that a copy of the above be sent to his family and printed in the *Boston Medical and Surgical Journal*.

Correspondence.

THE CHARLES RIVER BASIN.

BOSTON, April 27, 1901.

MR. EDITOR: — The insanitary condition of the Charles River basin, below the Watertown dam, must be admitted. Extensive areas of foul-looking and vile-smelling flats, rapidly increasing, are uncovered at low tide in the river, and, although it would be difficult to prove this condition to be a cause of sickness or of any specific disease, it may be affirmed, without fear of contradiction, it constitutes a nuisance at times, under favorable conditions of wind, tide and temperature, which demands early abatement.

The minor causes contributing to the offences are three:

(1) The common practice of dumping into the river, during the winter and spring, street detritus, including horse dung, under the permit annually granted by the Harbor and Land Commissioners for this disposition of snow and ice. During the past five years the writer has observed, time and time again, load after load of this material containing scarcely a vestige of either snow or ice, thus disposed of by the Street Department of the city of Boston.

(2) The dumping of ashes close to the sea wall back of Beacon Street. For about two years this has been a common practice, resulting in washing into the river with every flood tide a quantity of this material.

(3) The houses on the north side of Beacon Street, for about a mile, have no other means for the disposal of sewage than to discharge it into the river. The total volume for ten months of the year, assuming there are 200 houses, 7 persons to a house, and 75 gallons of sewage per capita per day, would be 31,500,000 gallons. For these three minor causes of present condition the remedy is obvious, and should be applied irrespective of the question of damming the Charles.

The major cause of the offence, amounting to many times all others combined, is the storm overflow of the South Metropolitan Sewerage System, which now occurs practically with every thaw or fall of rain. The magnitude of this source of pollution may to some degree be appreciated by briefly outlining the plan of the intercepting system of Boston, built for and by the city.

It was assumed there would be 20 square miles tributary to the system before a high-level sewer would be required. Twelve below Grade Forty, and 8 above, in which the prospective population was estimated to ultimately reach 800,000, producing 75 gallons of sewage per day per capita, or 60,000,000 gallons in the aggregate. Provision was made for rainwater, equivalent to one-fourth of an inch in twenty-four hours per acre, on tributary area, by increasing the capacity of the system 100% above the maximum dry weather flow. A rainfall or thaw exceeding one-fourth of an inch in twenty-four hours was provided for by regulating gates at the junction of the common sewers with the intercepting, which operate to discharge their contents along the water front. The gates are opened by a rise of sewage in the intercepting system above a certain level.

The first year (1884) the system was in full operation, when but a part of the common sewers were connected, these gates were opened 24 times. Since then no record has been kept, either by the Metropolitan or Boston sewerage authorities, of the number of times the discharge takes place. The dry weather flow of the sewage in 1884 was about 24,000,000 gallons per day. The dry weather flow at the present time varies from 55,000,000 to 75,000,000 gallons, influenced in measurement to some degree by defective action of the pumps at the calf pasture.

To this system Boston has added, since 1888, not less than 132 miles of common sewers, and, through the action of the legislature in creating the South Metropolitan Sewerage District, a drainage area of 51 square miles was added to the original 58, in which the mileage of sewers now connected is 307, making a total of 439 miles increase since 1888.

What proportion of the total miles of sewers are built on the separate system, and what proportion on the combined, is immaterial for the purpose of this communication, as the evidence is conclusive the system has for many years been overburdened. Recognizing this fact, in 1898, the Metropolitan Commissioners asked the legislature for authority to construct a high-level sewer, to tap the intercepting system at the corner of Ruggles Street and Huntington Avenue, and, through a force main, from a pumping station on Ward Street, deliver the sewage into a high-level sewer, 34 feet above mean low water, on Alphonsus Street. From this point the sewage is to flow by gravitation through Jamaica Plain, Hyde Park, Milton and Quincy, to about a mile beyond Nut Island, and discharge in the harbor, 15 miles from the starting point. A part of this sewer is under contract and now in process of construction, and is estimated to cost $4,500,000. To what extent, if any, this will relieve the present storm overflow in the Charles River is uncertain, as no study has been made of the question. One excellent authority says it will accomplish something in this regard. Another, equally as good, says, "By the time it is put in operation, the enormous excess of storm flow above the capacity of both systems, and the addition of tributary sewers under construction or projected, will prevent any appreciable diminution of the present volume or frequency of discharge into the river."

In 1894 the Harbor and Land Commissioners in the investigation of the then proposed Charles River dam, endeavored to ascertain the volume of this discharge and what influence it would have on the proposed basin.

No reliable data was obtainable as to volume. Mr. Stearns thought it amounted to .80 of 1%, and would equal the constant discharge of 3,000 persons if the total number in the district drained was 300,000, and that of 6,000, with a population of 600,000. Mr. Mattice, basing his estimate on maximum pumping capacity at the calf pasture, and the number of days in the year 1893, when the rainfall exceeded one-fourth of an inch, concluded an overflow would take place 37 times, and the total volume amount to the entire sewage of Boston for two and three-quarter days. The fact of the pumps being badly out of repair, and therefore incapable of doing anything like their presumed maximum work, seriously impaired the value of this estimate.

Professor Porter estimated the yearly volume discharged to be equivalent to twelve days' flow of the sewers connecting with the river. I testified to the fact of having kept a record of overflow of the Hereford Street sewer for ten months of 1893, and that it took place 46 times, and having personally observed many times the overflow at St. Mary Street, and in the Fens where Stony Brook enters; a flow of 20,000,000 gallons in twenty-four hours was not uncommon and, had I known what I have since learned of the backward flow in the trunk sewer above Gainsborough Street, I should have guessed considerably higher; for this means the entire flow of the system above, estimated at 20,000,000 gallons per day in dry weather, goes into river at St. Mary Street, and there are 15 other places where sewers overflow into the river between Craigie's bridge and Brighton, not including those on Stony Brook.

It will be remembered the city of Boston borrowed $25,000 to dredge the Fens basin two years ago. The work was done by a hydraulic dredge, which discharged the material at the Beacon Street sluiceway. The basin was presumed to be made 7 feet deep. Since that work, Stony Brook has flowed enough sewage and silt to form a bar just below the bridge, covered now only by from 3 to 6 inches of water at Grade Eight. To prevent further accumulation, a survey has been made for a sewer, beginning at what is now the end of Stony Brook and finally discharging into the river through an opening in the structure erected on the sea wall west of Charles Gate.

Relative to the effect of the storm flow of sewage on Charles River basin if the dam were built, there was a wide divergence of opinion expressed at the hearing, the weight of which I am disqualified to measure, having expressed an opinion, a dam such as proposed would nullify the plan for flushing the Fens basin with every available tide in warm weather, and without this the region would be rendered uninhabitable by the large amount of sewage discharged there. Mr. Stearns, when questioned on this matter, said, "Stony Brook might be diverted to the Charles, and if necessary a propeller might be employed to create a current in the Fens water. Regardless of what may be the best remedy for existing conditions, it must be apparent that storm water is the primal cause of the difficulties.

In this journal of March 12, 1891, will be found the following, relative to the admission of storm water to Boston's system: "With the rapidly increasing population the city, and the extensions now under construction designed to accommodate the inhabitants of Waltham, Newton, Watertown, Brookline and Brighton, large volumes of sewage must in time of storm be discharged into the Charles River basin or be conducted to the outfall. . . . In the interest of economy, and the sanitation of the river and upper harbor, it is high time we ceased to construct what is known as the combined system and adopt what Colonel Waring introduced at Memphis, and known as the 'separate system.' For it seems the height of folly to conduct the rainwater falling on the roof of my house to the pumping plant at the calf pasture, where it must be elevated 32 feet before it can be disposed of, when it might be discharged by gravitation in a natural water course within 200 feet."

It does not seem to be strong language to add, in light of our experience, that what appeared to be folly ten years ago is now madness.

HENRY J. BARNES, M.D.

METEOROLOGICAL RECORD.

For the week ending April 27th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,892; under five years of age 837; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 701, acute lung diseases 430, consumption 376, diphtheria and croup 99, diarrheal diseases 44, scarlet fever 63, influenza 10, typhoid fever 29, whooping cough 22, measles 14, cerebro-spinal meningitis 22, smallpox 9, erysipelas 19.

From whooping cough, New York 6, Philadelphia 3, Baltimore 1, Pittsburg 4, Boston 4, Lowell 2, Holyoke 1,

Chelsea 1. From cerebro-spinal meningitis. New York 6, Baltimore 1, Providence 1, Boston 5, Worcester 3, Lynn 1, Salem 2, Pittsfield 1, Beverly 1, Framingham 1. From scarlet fever, New York 44, Philadelphia 8, Pittsburg 1, Providence 1, Boston 7, Lowell 1, Haverhill 1. From typhoid fever, New York 7, Philadelphia 7, Baltimore 2, Pittsburg 6, Boston 4, Fall River 2, Clinton 1. From measles, New York 9, Pittsburg 2, Boston 3. From erysipelas, New York, 9, Philadelphia 4, Baltimore 3, Pittsburg 1, Boston 2. From smallpox, New York 8, Philadelphia 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending April 13th, the death rate was 19.2. Deaths reported, 4,339; acute diseases of the respiratory organs (London), 345, whooping cough 130, diphtheria 68, measles 112, fever 19, scarlet fever 31.

The death rate ranged from 11.2, in Croyden, to 25.0, in Liverpool; Birkenhead 15.7, Birmingham 21.8, Blackburn 21.7, Bolton 17.6, Bradford 18.9, Brighton 19.2, Bristol 20.3, Burnley 20.3, Cardiff 11.6, Derby 18.1, Gateshead 19.5, Halifax 18.5, Huddersfield 16.3, Hull 16.9, Leeds 19.0, Leicester 21.4, London 18.3, Manchester 24.2, Newcastle-on-Tyne 23.7, Norwich 19.3, Nottingham 17.4, Oldham 21.4, Plymouth 18.1, Portsmouth 16.2, Preston 23.9, Salford 20.8, Sheffield 20.4, Sunderland 22.0, Swansea 16.5, West Ham 12.3, Wolverhampton, 17.9.

RECENT DEATHS.

DR. SAMUEL G. DORR, postmaster of Buffalo, N. Y., died on April 28th. He was born in Dansville, N. Y., in 1840, and had practised in Buffalo since 1875. He was appointed postmaster in 1899.

DR. ABRAHAM DEYO, a prominent physician of Ulster County, N. Y., died at Gardiner, N. Y., on May 4th at the age of seventy-one. He was a graduate of the University of the City of New York and of the College of Physicians and Surgeons, New York.

DR. SAMUEL K. LYON, a highly esteemed practitioner of New York and for thirty years a surgeon of the Police Department, died suddenly from pulmonary hemorrhage on May 4th. He was a native of New York and sixty-three years of age. After graduation from Columbia College he studied medicine with Dr. Willard Parker, and received the degree of M.D. from the College of Physicians and Surgeons, New York, in 1866.

SOCIETY NOTICES.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. — The fifty-seventh annual meeting of the American Medico-Psychological Association will be held at Milwaukee, Wis., June 11 to 14, 1901.

AMERICAN CONGRESS OF TUBERCULOSIS. — The American Congress of Tuberculosis will be held at the Grand Central Palace in the city of New York, May 15th and 16th, and perhaps May 17th, 1901. In joint session with the Medico-Legal Society of New York.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — A regular meeting of the Society will be held at 3 Park Street, Boston, Mass., on Thursday, May 16, 1901, at 7.30 P.M.

Papers: Dr. Emily Upham, "A Peculiar Case of Malaria." Dr. Harriet E. Lothrop, "The Pathology of Malaria; Diagnosis by Blood Examination."

Discussion: Dr. Mary F. Hobart, "Malaria as Met in General Practice in and Around Boston." Dr. Elizabeth T. Gray, "Malaria as a Complication in Surgical Work."

DR. AGNES C. VIETOR, Secretary,
Trinity Court, Boston.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED MAY 2, 1901.

D. A. CARMICHAEL, surgeon, to assume temporary command of the San Francisco quarantine station, April 27, 1901.

C. P. WERTENBAKER, passed assistant surgeon, to proceed to Prescott, Ark., for special temporary duty, April 27, 1901.

J. B. GREENE, passed assistant surgeon, detailed for temporary duty in the Bureau, April 29, 1901.

V. G. HEISER, assistant surgeon, to proceed to Norfolk, Va., for special temporary duty, April 27, 1901. To proceed to Quebec, Canada, and report to the United States Commissioner of Immigration for duty, May 1, 1900.

W. F. SCHLAAR, hospital steward. Granted leave of absence for twenty-six days, March 29, 1901.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, WEEK ENDED MAY 4, 1901.

B. L. WRIGHT, assistant surgeon, ordered to the Massachusetts, May 1st.

S. S. RODMAN, assistant surgeon, detached from the Adams, May 11th, and ordered to the Alert.

H. L. LAW, surgeon, retired, detached from the Recruiting Rendezvous, Buffalo, N. Y., and ordered home.

THE TREATMENT OF PSOAS ABSCESS BY INCISION.

BY ROBERT W. LOVETT, M.D., BOSTON.

The treatment of psoas abscess has been extensively discussed, and rather widely-differing views are held by men of experience. It was thought that, possibly, the investigation of a group of cases occurring at the Children's Hospital might be of value in contributing to the question of the value of treatment by incision. The group of cases taken for investigation were those occurring on the second surgical service at the hospital, between July 1, 1890, and July 1, 1900, making a period of ten years, and all cases admitted to the service with psoas abscess during that time were considered.

The cases were all treated under the same conditions by the same surgical staff, and any value that they may have consists in the fact that all cases were included, and that in the majority of them the end result can be reported. The writer is indebted to his colleagues for their permission to publish their cases.

The questions arising are, of course, these: (1) What is the result of incising psoas abscesses so far as life and function of the limb are concerned, and (2) if incision is advisable, what is the best method of operation?

In the period just mentioned, 54 cases of psoas abscess were admitted to the wards. Five were not operated upon; 49 were operated upon. Of the 54 cases, it is possible to report on the present condition of 47; that is to say, to report on their condition some time in the late fall of 1900 or winter of 1900–1901.

Of the 5 cases not operated upon, 2 were treated expectantly and recovered permanently; the third was in such poor general condition that operation was not deemed advisable and the child died five months later without operation. The fourth died of intercurrent appendicitis while waiting for operation. It was, apparently, in no way connected with the abscess. The fifth case was treated expectantly, the present condition is not known.

Sex. — Of the 54 cases, 32 were boys, 21 were girls, and in 1 the sex was not stated. In Young's[1] group of 78 cases of Pott's disease complicated with abscess, there were 52 males and 26 females. This predominance of males over females is not characteristic of Pott's disease in general. In 4,670 cases from Gibney, Fisher, Taylor, Vulpius and the Children's Hospital, there were 2,405 males and 2,265 females.

Age.—The age of the children ranged from two and one-half to fourteen. Twenty-two cases were under six, and 6 cases were over ten. There seemed to be no especial predisposition toward any one age.

The *duration* of the disease at the onset of the abscess showed very little. Accuracy could not be expected from that class of patients, and it is well enough known that psoas abscess is a late rather than an early complication of Pott's disease. In 24 cases the duration was given as of periods varying from two to five years, and in the remaining cases the period was either stated as being shorter or was not known. As in many cases, the abscess was one of the first symptoms to call attention to the disease, such figures, when dealing with short periods, are unreliable.

Location of disease. —The location of the vertebral disease was as follows: Dorsal, 11; dorso-lumbar, 17; lumbar, 23; not stated, 3; making 54. Young's cases were as follows: In 74, dorsal, 43; lumbar, 31. Dollinger,[2] in 138 cases, found 44 in the dorsal region and 94 in the lumbar. It is interesting, in this connection, to note that Dollinger places the percentage of abscesses in the different regions of the spine as follows: Among cervical cases, 20.6 developed abscess; in dorsal cases, 11.6; and of lumbar cases, 40.1. Rushton Parker, collecting statistics of the occurrence of abscesses, estimated that 8% of dorsal cases developed abscess, 30% of dorsolumbar, and 70% of lumbar cases. These latter statistics are from a much smaller number of cases than those of Dollinger, as Parker generalized from 140 cases instead of from 700, as Dollinger did. The statistics, however, are of only relative value in either case.

Site of abscess. — The abscess occurred on the right side 21 times; on the left side 24 times; 4 times on both sides; and in 5 cases its location was not definitely stated.

The abscess presented in the iliac region 27 times; in the lumbar region (in the back) 15 times; in both lumbar and iliac regions 5 times and in the gluteal region 6 times.

The number of lumbar abscesses in this group is surprising and differs from other statistics, yet there is no reason to question the accuracy of the statement that the abscess appeared as a swelling on the back. Young reports 63 psoas and 21 lumbar abscesses, and Dollinger 123 psoas, 9 lumbar and 6 gluteal.

Temperature. — The temperature before operation was high in 12 cases and practically normal in 37. Its character was not stated in 5. This statement is based on an examination of the charts in each case, as they were incorporated in the records. It, therefore, justifies the statement that the majority of cases show no rise of temperature in connection with the abscess. An attempt was made to see if cases in which the temperature was high before the operation showed a higher mortality than in cases which were not high, with the following result:

Of the 12 cases where the temperature was high 7 were dead, 3 were alive and 2 were not heard from, making a percentage of 70 mortality where the result was known. Of the 34 cases where the temperature was practically normal, 10 were dead, 23 alive and 4 not heard from, making a mortality percentage of 33 where the result was known.

Although it is hardly justifiable to draw any definite conclusions from such a small group of cases, it is suggestive that in these 2 groups the mortal-

[1] E. B. Young, Boston Medical and Surgical Journal, cxliii, 19, 470.

[2] Die Behandlung, der Tub. Wirbel. Stuttgart, 1896.

ity was 70% where the temperature was high before operation, and only 33% where it was normal. Yet the cases where the temperature is high are probably the ones most urgently requiring operation.

The record of the bacteriological examination of the pus was unfortunately not kept in most of the cases. In only 6 was there a record, and in all those reported on it was sterile. The blood count, also, was only reported on in 10 cases, and in only 2 out of the 10 was the leucocyte count over 12,000.

Mode of operation. — The cases were next examined to see if any one mode of operation appeared to be better than the others.

The modes of operation were practically 3: Either a simple incision in the iliac region, a simple incision in the lumbar region, or an incision in both iliac and lumbar regions.

In practically all of the cases, drainage was obtained by a tube or by gauze, aud the abscess was not allowed to close immediately after operation.

As a rule, no extensive attempts were made to remove the pyogenic membrane, but the abscess was opened, wiped out by gauze or possibly washed out, or, in many cases, simply emptied and dressed.

If one may draw any conclusion from so small a group of cases, the evidence was strongly in favor of a single incision in either the iliac or lumbar region, and was against the double incision in both iliac and lumbar region. It is only fair to add that the cases operated on by the double incision were probably the worst cases in the series.

	Dead.	Alive.	Not known.
Of 13 cases opened by incision in iliac region	3	8	2
Of 14 cases opened by incision in lumbar region	4	9	1
Of 15 cases opened by incision in both lumbar and iliac regions	9	4	2
Of 6 cases opened by incision in gluteal region	1	4	1

This coincided exactly with my own experience in the matter, and I had for a year or two abandoned the double incision except when necessary. Dollinger had come to the same conclusion, and found that the less the abscess cavity was stirred up after incision the better. He opens by an incision in the iliac region 5 or 6 centimetres long, wipes the pyogenic membrane with dry tampons, does not irrigate the cavity, and drains with a thin tube, which is removed on the second or third day. I have pursued for the last year a somewhat similar method with the most satisfactory results that I have obtained in psoas abscess. The abscess is opened by a small incision inside of and near the anterior superior spine of the ilium. Its contents are emptied, the wound is sometimes irrigated and sometimes not, and it is drained by a tube. The second or third day after the operation, a plaster jacket is applied to the child, and in a day or two more he is placed in a sitting position. At the end of a week or two more, if he is in good condition, he is allowed to walk in moderation. It would, I think, be advisable if the affected leg were fixed in a plaster of Paris spica bandage in a position of extension, as suggested to me by Dr. Dane, to prevent flexion of the leg and consequent irritation of the muscle. By a large hole cut in the jacket, antiseptic dressings can be applied when necessary. My own experience has not been favorable to the early removal of the drainage tube, but Dollinger's reports seem convincing. A tube seems more satisfactory than gauze, which may merely plug a small opening.

A consideration of the figures to follow will show that recumbency of weeks or of months followed the operation in most cases. Also that death came long after operation as a result of general wearing out. It would seem natural, therefore, to try to discount these results by making the period of recumbency the shortest possible one, and by making the drainage efficient and free from the start. The iliac incision followed by the upright position, thereby making it the dependent point in the abscess cavity, seems best to fulfil these conditions, and it would seem as if the conditions for recovery were better.

After treatment. — With regard to recumbency after operation, in 45 cases where the notes were definite in that regard, the period was as follows. Two to four days, 4 cases; two weeks, 3 cases; two to four weeks, 8 cases; one to two months, 19 cases; two to seven months, 11 cases.

A *hectic* temperature developed after operation in 22 of the cases; there was no temperature that could be spoken of as hectic in 24; and it was not stated in 8.

Fecal fistula was noted in 4 cases. In all the cases, it was associated with those cases operated upon by the double incision (that is, one in the iliac and one in the lumbar region) and in 3 of the cases where the termination was known it proved fatal; in the fourth case the termination was not known.

Time of death.—In 14 cases where the time of death was known, the period showed very little, except that the majority occurred more than one year after operation. One case died six weeks after operation; 2 cases, six months; 3 cases, one year; 8 cases, one and a half to eight years.

Cause of death. — Nephritis caused death in 5 cases; tuberculosis meningitis in 2 cases, and 1 case died suddenly, without warning, six months after operation, in the Convalescent Home of the hospital. No autopsy was allowed, but it was thought that death was probably caused by a thrombus. In the other cases the cause of death could not be definitely stated.

Mortality.—Of the 49 operative cases, 17 (35%) are known to have died; 26 were alive in the early winter of 1900–1901, and the results were not known in 6 cases. It was thought that the mortality would probably be highest in those cases operated upon prior to 1896, because in these unfavorable results would have had time to develop. Of 20 cases operated upon prior to 1896, 10 died (50%), 6 lived, and in 4 the termination was not known. Of 34 cases operated upon from 1896 to 1900, 9 died (26%), 22 lived and 3 not known. In the group of cases operated upon prior to 1896, the mortality was 50%. These cases would seem to have the right to be considered as late results, as

in no case had less than five years elapsed since operation, whereas, if recent cases only are considered (that is, cases within five years), the mortality per cent. falls to 27.

Functional results. — It is possible to speak of the present condition of 26 of the cases. The sinuses are open in 9 cases and closed in 17. With regard to the general condition of these patients, of the 26 cases, 12 are well; that is to say, the sinuses are closed; they no longer require apparatus; they attend school or are at work, and they suffer practically no disability as the result of the psoas abscess. The general condition may be classed as good in 10 of the other cases. In these cases treatment is going on; they are making good progress; the sinuses are closed in some of them and open in others. The general condition was classed as fair in 3 and as bad in 1.

Other operative methods than incision have not been considered because they have not been used in this particular group of cases.

In children, the aspiration of the contents of the abscess is, of course, not practised as much as is necessary in adults. The aspiration of the abscess contents and filling with iodoform has not found a place in the hospital routine, and although extraordinary results are published by Bruns, Frænkel and others, the operation by incision, after expectant treatment has failed, has been the one regularly done at the hospital. The results, so far as mortality and functional results are concerned, seem to make it appear a justifiable operation not attended with an unreasonably high mortality per cent. in a disease whose mortality per cent. is high without operation.

The practical conclusions of this paper, so far as one can generalize from so small a number of cases, are: That fever is not necessarily an accompaniment of psoas abscess formation; that where it does occur, the prognosis is not so good as where it is absent; that the best method of operation is by a lumbar or an iliac incision, one or the other, and preferably the latter. It seems, on general principles, desirable to avoid recumbency for long periods, which, of course, makes drainage by an iliac incision almost impossible. It seems, therefore, best to put on a plaster jacket almost immediately after operation to enable the patient to sit erect and to enable the abscess to drain almost from the first. In this way the writer has obtained better results than by any other method.

INFANTILE SCORBUTUS.[1]

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON,

Instructor in Diseases of Children, Harvard Medical School; Assistant Visiting Physician at the City Hospital and at the Infants' Hospital, Boston.

DEFINITION.

Scorbutus is a constitutional disease associated with imperfect nutrition and due to some prolonged error in diet. It is characterized by anemia and a tendency to hemorrhage.

[1] Read at the Annual Meeting of the Bristol North District Society, April 18, 1901.

Infantile scorbutus has been but comparatively recently recognized. It was first described by English writers, notably by Barlow in 1883. It was brought to the attention of the profession in this country by the admirable paper of Northrup and Crandell in 1894. Since then many cases have been reported. The committee of the American Pediatric Society in 1898 collected 379 cases. Many have been reported since then. It is probable that many cases have not been reported in the last few years, as the interest in the disease has been less active since its more general recognition. While the more marked cases are now usually recognized, the milder cases are still often overlooked and misunderstood. It is uncommon under six months, and rare after two years. About two-thirds of the cases collected by the American Pediatric Society occurred in the last six months of the first year.

ILLUSTRATIVE CASES.

The following cases illustrate the symptomatology of the disease better, I think, than any detailed description of symptoms, although it may possibly be well to briefly sum up the symptoms later:

Case I. Eva McK., was born March 8, 1898. When about a week old she had hemorrhages from the gums, genitals and gastro-enteric tract, which were, undoubtedly, due to hemorrhagic disease of the newborn. She recovered and then did well until about the middle of August. She was fed on Horlick's Malted Milk mixed with water. About the middle of August, when six months old, she became "sore all over." Any motion or handling seemed to cause pain. Four or five days later swelling was noticed about the knees and, soon after, about the ankles. Still later, swelling appeared about the wrists and then about the shoulders. For several days before she was seen she had passed a little blood from the bowels. Her mouth began to bleed the day before. She passed but little urine, which was not red.

Physical examination. — She was small and poorly nourished. Pallor was marked. Her expression was that of great fear. There were no teeth. The gums were not swollen or discolored. The hemorrhage came from a slight ulceration in the frenum of the tongue. There was swelling near the sternal ends of both clavicles. There was no depression of the sternum. The heart and lungs were normal. She lay on her back with a slight general kyphosis of the spine. The back was apparently tender. The shoulders were arched, the arms flexed at the elbows and the hands clenched. There was swelling over the upper ends of both humeri and about the shoulder joints. There was also marked swelling over the lower part of the diaphysis of both bones of both forearms. There was no redness or heat. The abdomen showed nothing abnormal. The liver and spleen were normal. The thighs were held flexed at a right angle and the knees at an acute angle. There was no swelling about the upper portions of the femora, but extension at the hips was sharply limited at a right angle. Only a few degrees of motion was possible at the knees. There was marked swelling about the lower ends of both femora, not involving the knee joints. The swellings were not red or hot. There was also marked swelling of the lower portion of the diaphysis of both bones of the right leg, and beginning swelling in the left leg. These swellings were not red or hot. All the swellings were tender. There were no subcutaneous hemorrhages. She was admitted to the Infants' Hospital and promptly recovered under treatment.

Case II. Helen M., was born December 3d. She never nursed, but was fed on Nestlé's Food for the first

three months. This was changed to Horlick's Malted Milk because of gastro-intestinal disturbance. She continued to take this until she was ten months old, when I first saw her. On this food the dejections were normal and she did not vomit. Early in July, when seven months old, it was noticed that she did not use her legs and that her feet were tender. A few weeks later she began to draw up both knees and soon held them completely flexed. The mouth began to be sore about the first of August. The tenderness in the legs increased steadily, and about the middle of September swelling was noticed in both knees, both ankles and both wrists. I first saw her October 8th, when she was ten months old. She had then been kept on a pillow for several weeks because of the excessive pain which any movement caused. Even bathing had been omitted for the last fortnight. She had been seen by many physicians, most of whom had considered the case "rheumatism," and some of whom had considered it "Pott's disease." All had given an unfavorable prognosis.

Physical examination. — She was fairly developed and somewhat emaciated. The skin was pale and dry. There were a few purpuric spots here and there on the body and extremities. Only the lower edges of the two upper middle incisors were visible, the body of the teeth being covered by the dark-purple, swollen gum. The same condition, but to a less marked degree, was present about the four lower incisors. The heart, lungs and abdomen were normal. She was unable to sit alone, but when supported, the spine showed a marked general kyphosis, greatest in the lower dorsal region. There were no signs of rickets beyond a slight rosary. Both wrists were swollen, the swelling being most marked about the lower epiphysis and diaphysis on each side. They were not tender or painful, and all the motions of the arms were normal. She lay on her back with the thighs flexed on the body and the knees flexed to a right angle on the thighs. There was a marked swelling about the lower epiphysis and diaphysis of the left femur, which was very tender but not hot or red. The same condition was present on the right, but to a less degree. No motion was allowed at the knees. The motions at the hips and ankles were normal. The child cried out in terror when approached, so great was her fear of being touched. She was given a carefully modified, pasteurized milk, and ordered to take the juice of a lemon daily.

In a week she could be moved a good deal without pain. The swelling at both wrists and knees was diminished, the knees were held almost extended, and could be flexed about three-quarters of the normal amount, while the mouth was much improved. In another week she had shed her pillow, was being bathed regularly, held her legs almost extended, and had begun to use them. Motion was completely normal in the right knee and almost normal in the left. The swelling at the knees was almost gone, and that at the wrists entirely so. The mouth was well and she had another tooth. She continued to improve rapidly.

CASE III. Marion S., was nursed about three months. She was then fed on Eskay's Food. As this did not agree, she was put on Mellin's Food with milk. She seemed to do fairly well until about twenty-one months old when she was beginning to walk alone. About that time she fell on the floor, and after this did not use the right side as well as formerly. She soon began to complain when her legs were touched. The tenderness in the legs steadily increased. She soon stopped walking, and later could not sit without support. Then she began to lose the use of the arms and legs. She soon kept the thighs and knees flexed and never extended them. Swelling of the arms and legs developed gradually. About five weeks from the time of the fall the gums began to swell a little, but did not swell much until a few days before she was seen. She had no hemorrhages. She lost much weight. She was first seen when twenty-three months old. At that time she was taking uncooked milk and water, Mellin's Food, Bovinine and eggs.

Physical examination. — She was fairly developed and nourished. Her color was fair. The fontanelle not quite closed. She had fourteen teeth. The gums were swollen and purple, especially about the back teeth. She moved her head freely. She was able to sit up without support, but her back was tender. She moved her shoulders and elbows freely. There was marked swelling of the lower part of the diaphysis of both ulnæ and both radii. These swellings were very tender, but not red or hot. She moved the wrists but little. She held the thighs and knees flexed. Extension caused pain but flexion did not. There was no swelling of the joints, but possibly a little about the lower portions of the tibiæ. There was slight edema of the feet and lower legs. There were no subcutaneous hemorrhages.

The diet was continued unchanged, but beef juice and orange juice were added to it. A letter was received a week later from the mother, from which the following are extracts: "She does not suffer, but is far from well yet. Her wrists are still swollen, but she can move them any way she wants to. Her gums are better. I can see a little improvement every day. She tries to stand up occasionally, but cannot bear much weight yet. She is happy and plays as she used to. We all think it is wonderful how she started to improve before she had taken the juice of a whole orange."

It would have been difficult for anyone having a knowledge of the disease to have mistaken the diagnosis in these cases. It was less evident, however, in the following one:

CASE IV. John C., was the eight months' old son of a physician, a specialist in diseases of the nervous system. He had always been fed regularly with proper amounts of a modified milk which had been vigorously sterilized, sometimes for several hours. He had always been well, but had taken less food for a month or two and had lost some weight. Two weeks before I saw him he had tumbled over on the bed and was thought to have doubled his legs under him. He cried a good deal for the next twenty-four hours and disliked to have his legs, especially the right, moved. He continued to have more or less pain and tenderness in his legs, and cried vigorously whenever moved. His father had made a probable diagnosis of infantile paralysis.

Physical examination. — He was fairly developed and nourished. The head was large and slightly rachitic in shape. There was a slight rosary and slight enlargement of the epiphyses at the wrists. He had no teeth and the gums were normal. He preferred to lie on his back with his right knee flexed, and cried out when the back or legs were moved, the right leg being the more tender. Passive movements were all normal, however, and the physical examination was otherwise negative. The temperature was, and had been, normal. The case was considered to be one of scurvy and the fall merely a coincidence. He was put on an uncooked, modified milk and given small doses of lemon juice. On account of the tenderness he was put on a Bradford frame, and the right leg put up in a light plaster. As he did not improve much in the course of a week the lemon juice was omitted, and he was given the juice of half an orange daily. The plaster was kicked off nine days later; the next day he was taken off the frame apparently perfectly well.

The delay in the improvement in this case was undoubtedly due to the insufficient size of the doses of lemon juice.

The next case might well have been overlooked, but was undoubtedly scurvy:

CASE V. Robert M., was born about May 1st. From the time he was a month old his digestion was extremely feeble. He was fed on a modified milk, which was both peptonized and pasteurized. He was doing well up to November 1st. He then began to cry out a little when moved. About November 15th his right leg

became very tender and he ceased to use it. Examination showed a little thickening about the lower end of the diaphysis of the right femur. The rest of the physical examination was entirely negative. The peptonization and pasteurization were both stopped, and at the end of a week motions were perfectly free, and there was no tenderness. There was still a little thickening. Orange juice was not given until this time. It was then begun in small doses as a precautionary measure, and continued for several weeks.

The following case is an example of the mildest type of the disease, a form which, I believe, is very common, and which is very often unrecognized:

Case VI. Catherine L., was born March 12th, several weeks premature. She was fed on a modified, pasteurized milk, but always had a very delicate digestion. In the latter part of November, when about eight months old, she began to cry if any attempt was made to let her sit up unsupported. Her mouth began to be a little sore, and in the course of a week the gums were swollen and purplish about the two lower teeth. She was ordered two teaspoonfuls of orange juice twice a day. The mouth was entirely well in a week and she could sit up without pain or discomfort.

Various symptoms which were not present in these cases may occur in the severer forms of the disease. Hemorrhages into the skin are not uncommon. They may occur from the gastro-intestinal tract or into the brain. Hemorrhages behind the eye may cause proptosis. Renal hemorrhage occurs occasionally.

SYMPTOMS.

Anemia and malnutrition.— Anemia and malnutrition are probably the earliest symptoms. There is nothing characteristic about them and they alone are not sufficient to warrant the diagnosis of scurvy. Their presence should, however, put one on one's guard.

Pain.— Pain is almost always the first symptom noted. It occurs on motion or on handling and usually not when the baby is quiet. It is not only the first symptom but the most persistent and the most constant. It increases steadily in severity. On account of the pain on motion the children are fearful of being touched. Their expression of abject terror when anyone approaches them is most characteristic. The pain is most often in the legs, next in the back, and next in the arms. As the result of the pain on motion they are unwilling to use their legs and arms. Hence paralysis is often suspected. The extremities are often held rigidly; the legs are usually held flexed at the thighs and at the knees.

Swelling.— As the disease progresses swellings of the limbs appear. These are more common in the lower than in the upper extremities, and more common in the thighs than in the legs. They are usually situated at the ends of the diaphyses and are pyriform and symmetrical in shape. They are usually tender, sometimes reddened, but never hot. They are due to subperiosteal hemorrhage. If the hemorrhage is extreme, separation of the epiphyses may result. Swellings very rarely occur over other bones than those of the extremities.

Gums.— Swelling, sponginess and ulceration of the gums are very common symptoms, but are almost always preceded for some time by pains and often by swelling of the extremities. The gums are purple and often hemorrhagic. The picture is that of stomatitis ulcerosa. It was formerly supposed that the gums were not involved unless there were teeth. In about one-half of the cases collected by the American Pediatric Society in which there were no teeth, the gums were, however, involved. In some cases redness and swelling of the gums precede the other symptoms and sometimes are the only manifestation of the disease. The prompt relief of these symptoms when the diet is changed or when orange juice is administered is proof of their scorbutic nature.

Hemorrhages.— Cutaneous hemorrhages are common in the severe cases. Hemorrhages from the nose, stomach and bowels are not very infrequent in the worst cases. Hemorrhage into the orbit may push the eyes forward, causing proptosis. Hemorrhages may also occur in the muscles or in any of the internal organs.

Urine.— Hematuria is a rare symptom, and albuminuria rather infrequent. Nephritis, however, sometimes develops.

Blood.— As already noted, anemia is one of the earliest and most constant symptoms. There is but little data as to the nature of this anemia. What little there is, however, shows that the characteristics are those of secondary anemia or of the anemia of hemorrhage.

Fever.— Fever is not a prominent symptom and is usually absent. When present it is probably due to accidental causes.

PATHOLOGY.

The pathologic lesions have already been mentioned in speaking of the symtomatology. They are briefly: Anemia, hemorrhage and stomatitis ulcerosa. As already detailed, hemorrhage may occur into the skin and mucous membranes and into any of the tissues or internal organs. The most characteristic form of hemorrhage is subperiosteal of the long bones. The femora are most commonly affected. Separation of the epiphyses may occur. Nephritis is an uncommon complication.

DIAGNOSIS.

In general the only thing necessary for the diagnosis of all but the mildest cases is a knowledge of the disease and of its symtomatology. If these are kept in mind it will seldom pass unrecognized. The diseases for which it is most commonly mistaken are rheumatism, purpura, rickets, syphilis, Pott's disease, infantile paralysis and injury.

Rheumatism.—Rheumatism is almost unknown at the age at which scurvy occurs most frequently. It is more commonly accompanied by fever, seldom by hemorrhage and almost never by stomatitis. Swellings are unusual in rheumatism at this age. If present they are in the joints instead of in the diaphyses, are hot and usually red. In case of doubt the quick response to treatment would soon settle the diagnosis.

Purpura.— In very severe cases of purpura the symptoms may be the same as in scorbutus.

In purpura, however, the swelling of the extremities are among the latest symptoms; in scorbutus, among the earliest. In purpura, stomatitis and hemorrhage into the skin and mucous membrane are the earliest symptoms; in scorbutus, among the latest. Mild cases of purpura, on account of sequence of symptoms, could hardly be mistaken for scurvy. The theraputic test would here also settle the diagnosis conclusively.

Rickets. — The diagnosis between scurvy and rickets is an easy one. If there is any question between the two the condition is almost certainly scurvy. Confusion could hardly arise except on account of swellings of the extremities. Swellings in rickets large enough to cause confusion would certainly be accompanied by a rosary and probably by deformity of the thorax and head. Moreover, they are at the junction of the epiphysis and the diaphysis instead of at the lower end of the diaphysis. They are not accompanied by stomatitis and hemorrhage and seldom by pain.

The diagnosis of scurvy complicating rickets is hardly more difficult. As a rule, pain and tenderness in rickets are due to a complicated scorbutus. The presence of stomatitis ulcerosa, hemorrhages and swellings about the diaphyses makes the diagnosis plain.

Syphilis. — Scorbutus could hardly be mistaken for syphilis. The swellings of syphilis are more chronic, less tender, and at the junction of the diaphysis and epiphyseal line. They are seldom associated with hemorrhage and never with stomatitis ulcerosa. In syphilis, moreover, there may be the history of the disease in the parent or in the past, and other characteristic symptoms are always present.

Pott's disease. — Pott's disease is rare in the first two years of life. The onset is very slow and the pain and tenderness not as extreme as in scurvy. It is not associated with swellings in the extremities, hemorrhage or stomatitis. There is usually a sharper deformity in the spine and often physical signs of tuberculosis elsewhere.

Acute anterior poliomyelitis. — The onset of infantile paralysis is acute and usually febrile. Pain and tenderness are unusual. If present they occur early and continue but a few days. There is no swelling. There is flaccidity instead of spasm. It is never accompanied by hemorrhage or by stomatitis. Muscular atrophy, loss of knee jerks and limitation of the paralysis soon develop.

Injury. — Injury might be suspected if the development of the scurvy was by chance associated with a fall or blow. The presence of other characteristic signs of scurvy should, however, prevent confusion.

Finally, an unaccountable stomatitis, general hyperesthesia and pain on being moved or taken up, especially if they occur in bottle-fed babies, should always arouse the suspicion of scurvy. If these earliest symptoms are recognized many miraculous cures later will be prevented, but the babies will be saved a good deal of unnecessary suffering.

ETIOLOGY.

Race and sex are unimportant. Age is an important factor, the majority of cases occurring in the second six months of life. It is probable that inherited feebleness, previous ill health and improper hygienic surroundings may predispose to the disease. The importance of improper hygienic surroundings cannot be great, however, as the vast majority of cases occur in well-to-do families. There has been much discussion as to the relation between rickets and scurvy. It is probable, however, that there is no real relation between them, although rickets may possibly act as a predisposing cause of scurvy by weakening the general resistance. The tenderness met with in rickets is probably almost always due to a complicating scorbutic condition. Acute rickets is scurvy and not rickets at all.

The chief, if not the sole, cause of infantile scurvy is to be found in the diet. It is difficult to say, however, to what error in diet scurvy is due. The majority of cases arise in babies fed on proprietary foods. On account of the great number of cases in infants fed on proprietary foods prepared without milk, and on account of the rapid recovery in many cases when uncooked milk is given, as well as the rapid response to beef juice and orange juice, it was supposed that scurvy was due to the lack of "freshness" in the food. As the disease has in several instances arisen in infants fed exclusively on breast milk or on raw milk, and recovery has taken place when the food has been changed from breast milk to sterilized milk and from raw milk to starchy foods, it is evident that lack of "freshness" cannot be the sole causative factor, although it may be an important one. In fact, it seems at present impossible to draw any definite conclusions as to what the element or elements in the food are whose presence or absence causes scurvy, for scurvy has developed on all sorts of foods, seemingly suitable or unsuitable as the case may be, and change of food sometimes from one apparently suitable to one apparently less so has been followed by recovery. It is probable, however, that the faults are either the lack of certain elements in the food necessary for nutrition or their presence in some non-assimilable form. The following conclusions of the Committee of the American Pediatric Society certainly seem within our knowledge. It is doubtful if any more specific ones are justifiable: (1) "The development of the disease follows in each case the prolonged employment of some diet unsuitable to the individual child . . . (2) in general, . . . the farther a food is removed in character from the natural food of the child the more likely its use is to be followed by the development of scurvy."

PROGNOSIS.

Death is not infrequent in unrecognized and untreated cases. Recovery is almost certain with proper treatment if the child is not too much reduced. Improvement is almost immediate, and recovery complete within two or three weeks.

TREATMENT.

The treatment is simple. It consists of regulation of the diet and the administration of orange or lemon juice. Many cases will recover on either method alone, but the combination is far preferable. The diet should be that suitable for the infant of the given age—breast milk, modified cows' milk, beef juice. Modified milk should, unles contra-indicated by complicating conditions, be given uncooked. The juice of a half or of a whole lemon or orange should be given daily. Scorbutic infants almost always take it with avidity. If they do not, they must be made to take it. It almost never disturbs the digestion.

No drug is of the slightest utility in the treatment of this disease. During convalescence iron may be indicated for the anemia. Complicating gastro-enteric disturbance should be treated symptomatically, if necessary.

The tenderness of the back and limbs demands that the infant be kept quiet. In the severer cases recumbency on a Bradford frame or light splints to the affected limbs will afford much relief during the first few days; they are rarely needed longer.

NEURITIS RECURRING AFTER ATROPHY OF BOTH OPTIC NERVES IN A CASE OF BRAIN TUMOR.

BY EDWARD R. WILLIAMS, M.D., BOSTON.

The patient, a woman twenty-two years old, began to have attacks of headache and vomiting in the autumn of 1897. During the following winter she was compelled to stop work on account of failing sight which was not improved by glasses. In the summer of 1898 she complained of vertigo and numbness of the right side. This dizziness caused her to stagger more or less when she started to walk, but after a few seconds this would disappear. She then sought relief at the eye-clinic of the Boston City Hospital. The hospital records read: "Double optic neuritis. Much swelling of each disc; arteries obscured, veins large and tortuous; typical, macular changes of albuminuric retinitis. Says urine has been examined and pronounced healthy." Since then her memory has failed somewhat.

In August, 1899, she consulted me at the Boston Dispensary. In addition to her rapidly failing vision she presented only obscure anemic symptoms. The heart and kidneys were healthy. Upon examining her eyes the pupils were found equal and responsive to light. Vision in each eye was only sufficient to count fingers at three metres' distance. In the right fundus there was a pronounced atrophy of the papilla, and old hemorrhagic spots in the macula. In the left eye there was a similar degree of optic atrophy, with old hemorrhages about the macula. She said her sight had grown rapidly worse since the beginning of the year. After a period of quiescence, the vomiting and headache recommenced, so that on October 24, 1899, she was admitted to the City Hospital with a diagnosis of probable brain tumor. At that time an examination of the eyes showed: The pupils equal, regular and responding slightly to light, muscular movements apparently normal. The patient states that she sees nothing with the left eye and with the right only objects held to the extreme temporal side. Heart and kidneys normal. There is no tenderness of extremities, no loss of force in arms and legs and no impairment of sensation.

I examined her eyes two days after admission to the hospital, and found that the atrophy of both discs had increased very materially since my last examination. The veins and arteries had both begun to appear threadlike. The left eye had no perception of light, while the right eye could still discern the movements of the hand only on the temporal side.

The day before her discharge on November 6th I made a second examination. The discs in each eye then showed a still further progress of the atrophy, the color was greenish-white, and both the arteries as well as the veins were reduced to fine, threadlike lines. There was some nystagmus and no perception of light in either eye when tested with the mirror.

During the month spent in the hospital all active symptoms again subsided, and did not reappear till after her return home.

Twelve days after her discharge from the City Hospital her condition was so serious that she was admitted to the Carney Hospital on November 19, 1899. Examination then showed: "Left pupil was much dilated; neither responded to light. No perception of light in either eye. Right knee jerk was absent; sensation was apparently diminished over both legs and body up to waist line; muscular sense impaired; delayed sensation in both arms; mental apathy, which probably accounted for the sensory disturbances." On the following day "the pupils were somewhat contracted but equal, and responded well to the light."

From that time on the woman remained in a semicomatous condition. When questioned it was very difficult to get replies, yet, after a few minutes, she would answer intelligently.

Dr. Kilburn examined her eyes two days before death and reported: "Double optic neuritis; more pronounced in the left eye. The veins were large and tortuous and the swollen discs gave a typical picture of neuritis. The coma increased, and the patient died on November 23, 1899."

The result of the post-mortem examination, performed by Dr. George B. McGrath, follows: "The base presents in the interpeduncular space and impinging upon the optic chiasm, a soft, friable, greyish-pink mass of about the size of a horse chestnut; this mass presses upon but does not invade the second and third cranial nerves. Incision into the lateral ventricles, made through the mesial surfaces of the hemispheres, reveals on the left side anterior portion of the ventricle, a mass, 4 x 3 x 2 centimetres projecting freely into the cavity of the ventricle, apparently originating from the region of the lamina terminalis, on the

anterior part of the corpus callosum; grayish-pink and friable. On the right side a mass of somewhat greater proportions which is continuous with the outer wall of the ventricle and extends backward into the central portion of the ventricle. There is some increase in the intraventricular fluid. Sections 2 centimetres thick, made at a point 15 centimetres posterior to the tip of the frontal lobes reveal a mass of irregular outline measuring 12 centimetres from before backward, 6 centimetres from side to side, and 5 centimetres from top to bottom; occupies the region of the third ventricle, extending slightly into the left lateral ventricle, into the right lateral ventricle, and backwards along the cavity of the latter to a point corresponding with the anterior border of the right pedunculus cerebri. At the level of the optic chiasm the mass, which has a somewhat pyramidal shape, with the base uppermost, extends downward through the interpeduncular space; this extension corresponds with the mass (above noted) seen upon the base of the brain. The mass on the right side anteriorly is continuous with the outer wall of the lateral ventricle, and with the corpus callosum, which latter in this region it seems to replace at about the middle of the brain, and from there backwards, the corpus callosum lies freely above the mass. The cavity of the left lateral ventricle is distended by the mass which compresses surrounding structures; the corpus callosum is pushed towards the left, the corpus striatum and optic thalmus downwards and outwards. The pressure exerted by the growth is still further evidenced in this region by the flattening of the second and third cranial nerves. The mass lies freely in the mid and posterior portions of the right lateral ventricle, and at no point, except in the anterior part of the ventricle, invades surrounding structures."

Among the symptoms in this case there are three points which are especially worthy of consideration: (1) The recurring neuritis following the atrophy of each disc; (2) the similarity in appearance between neuroretinitis caused by brain tumor and a chronic nephritis; (3) the mildness and indefiniteness of all the symptoms, both ocular and general, as compared with the amount of change in the brain.

The double optic neuritis was first discovered about fifteen months before the death of the patient, and when seen, about one year later at the dispensary, the disease had terminated in a moderately well developed optic nerve atrophy in each eye. Finally, this condition changed again to an active inflammation, so that when the eyes were examined, two days before death, a pronounced neuritis was found, more developed in the left than in the right, but still in an early stage. Recurrence of a neuritis in an atrophied nerve is an extremely rare phenomenon, and I have only been able to find 2 cases reported in the literature. Gowers[1] says that "if a disc has become completely atrophied it is very rarely again the seat of inflammation. In 1 case, however, of a boy, age twelve (under the care of Dr. Hughlings-Jackson), who had double optic atrophy and absolute blindness due to intracranial disease some years previously, distinct double papillitis occurred in the atrophied discs, associated with symptoms of intracranial tumor. When, however, atrophy is partial or absent, in rare cases 2 attacks of neuritis may occur. In 1 case, for instance, a patient suffered without doubt from a cerebral tubercle, and died from an attack of tubercular meningitis. The former had probably become quiescent, and the neuritis which it caused subsided, leaving partial atrophy. The discs again became swollen and obscured with the symptoms of meningitis." It is interesting to note that in his earlier 1879 edition, Gowers says at the beginning of the corresponding paragraph, "if a disc has become completely atrophied it is *never* again the seat of inflammation, etc."

The only other case of this kind that I have found reported is by de Schweinitz and Thomson.[2] The patient, a man, first sought relief from attacks of epilepsy which had begun two years before. A cerebral tumor was suspected. At first there were no abnormal ocular symptoms except passive hyperemia of the retinal vessels and infiltration of the lymph sheaths. One year later there was a distinct congestion of both optic discs. When he was examined again, after still another year had elapsed, a well developed optic neuritis was noted. The vision in each eye was normal, as were also the fields for form and color. An attempt was made to relieve the constant headache by trephining the skull, but this gave only temporary relief. Soon after this operation, a progressive optic nerve atrophy commenced, which developed more rapidly in the left than in the right eye. In each macula there was a degeneration which resembled very closely albuminuric retinitis, but the urine was negative. About one year after the operation, the vision in the right eye was still normal, but in the left $\frac{3}{200}$. At that time a very temporary improvement in the circulation of each papilla was noted. The visual fields and color perception remained normal. Soon afterwards the patient began to have a return of the epileptic attacks as well as headaches, after which his sight began to gradually grow dimmer. The last examination of his eyes was made about three months following the final outbreak of active symptoms. The pupils were dilated, did not react to light or accommodation and there was absolute blindness. The papillæ were enormously swollen (+ 6 dioptres each eye) and both eyes presented a typical picture of optic neuritis. The central degenerative spots in both maculæ were still visible. It is interesting to note that although the papillæ were swollen to + 6 dioptres, the sight did not begin to fail till the subsequent atrophy had commenced.

This case resembles mine in having a neuritis recur after atrophy of both discs, and in the resemblance of the fundus change to retinitis albuminurica.

[1] Medical Ophthalmoscopy, 1890, p. 57.

[2] Arch. Ophthal., 1895, vol. xxiv, No. 2.

These 3 cases of recurring neuritis must not be confused with another kind which is rather more frequently seen. A second attack of neuritis may occur very rarely in cases of albuminuric retinitis, as noted by Uhthaff.[3] Gowers[4] describes a cerebral tumor case in which, after the papillitis subsided, the disc had a normal appearance till shortly before the death of the man, at which time a recurrence of the neuritis was noted. Marked improvement in the patient's general condition accompanied the subsidence of the neuritis.

It is important to note that when this case was first seen at the City Hospital, the changes in the fundi, especially the maculæ, were noted as typical of retinitis albuminurica. It is a fact that the same appearance of neuro-retinitis or neuritis may be caused either by brain tumor or chronic interstial nephritis. Burr[5] in a recent article, draws attention to the possibility of mistaking the cause of either fundus appearance. He cites a few cases of chronic nephritis, causing simple neuritis, which were considered by the oculist to be due to brain tumor. Græfe and Sæmisck[6] say that a papillitis with or without brain tumor may occur and therefore may exactly resemble a neuritis as seen in brain tumor. Wadsworth[7] maintains that the same or very similar fundus changes may be seen in cases of leucocythemia, (probable) meningitis, or diabetes. It seems, therefore, that neither is the stellate figure about the macula typical alone of chronic nephritis, nor is the simple neuritis indicative only of brain tumor. A few cases have been reported by Schmidt and Wegner, Bruns and von Græfe,[8] in which it was conclusively shown that the ophthalmoscopie picture (although practically identical with that seen in retinitis albuminurica) was caused by a cerebral tumor. There was no renal disease in any one of these cases.

The first one, by Schmidt and Wegner, was a woman of twenty-three years who first complained of headache, vomiting, dizziness and gradually failing sight. The fundus of the left eye showed the papilla swollen and red with indistinct edges. A light gray infiltration lying close to the edge of the papilla and also encroaching on it, covered the vessels in part of their course. There were also white spots characteristically arranged and hemorrhages about the macula. In the right eye the papilla had a clearer edge than in the left, but was of a grayish-red color. The veins were tortuous. Diagnosis: Retinitis albuminurica. No cardiac or renal symptoms present. The swelling from the exudates in each papilla increased and the diagnosis was changed to neuroretinitis in each eye. The vision decreased somewhat during this time. Nasal scotomata were found with the perimeter. No albumin was found in the urine at this time, and the physician under whose charge she had been at first, stated that the repeated tests for albumin had always been negative. The post-mortem examination showed a gliosarcoma situated in the left lateral ventricle.

The second one, cited by Bruns,[9] was a man thirty-six years old. There was a neuritis with swollen veins and white spots with hemorrhages distributed all over the retina. It was a typical picture of albuminuric retinitis. No albumin was found in the urine. At the autopsy a tumor of the frontal lobes was found; the kidneys were normal.

The third case was reported by von Græfe.[10] The boy, sixteen years old, was examined by a reliable physician, who made a diagnosis of albuminuric retinitis. A later and more careful examination by von Græfe showed that (1) the white spots were thicker and more confluent about the papilla than in typical Bright's disease; (2) the general swelling of the retinal tissues about the papilla was greater; (3) the papilla showed a steep-sided swelling (although the disc may be involved in Bright's disease, yet it hardly shows, with the opthalmoscope, a marked swelling); (4) the veins were greatly dilated, tortuous, and the papilla thereby was enormously reddened. There was no albumin and no renal symptoms. The tumor symptoms, in addition to the cardinal ones, included epileptic attacks, noises in the head, finally contractures of the neck muscles and sleepiness. Vischow found at the autopsy a medium-sized myxoma on the posterior border of the convexity of the right hemisphere.

It is surprising to note, in the present case, how indefinite and mild the clinical symptoms were, when one considers the great size of the tumor. A large part of the corpus callosum was totally destroyed, and the apex of the new growth appeared in the interpeduncular space, where it compressed the second and third cranial nerves. The only effect on the third nerve was to irritate it sufficiently to cause a temporary dilatation of the left pupil. There was no paralysis of the eye muscles.

Clinical Department.

A CASE OF ACCIDENTAL INOCULATION OF CANCER IN A FRESH WOUND.

BY A. T. CABOT, M.D., BOSTON,
Surgeon to the Massachusetts General Hospital.

At this time, when the investigation of cancerous disease is being pushed so earnestly, it is important to publish all facts which may throw light upon the etiology of the disease. The following case is presented as an instance of auto-inoculation of cancer. The case has been already published and a description of the operation has been given in a former article. Of this, only so much will be repeated here as is necessary to make plain the evidence proving this to be really a case of auto-inoculation.

The patient was a man of fifty-nine, with a cancer high up on the anterior wall of the rectum. An opening was made through a Kraske incision into the rectum posteriorly. The cancer was dragged down into this opening, and removed through it. During this manipulation the cauliflower-like juicy growth was rubbed about in close contact with the wound made by the Kraske operation.

All this occurred in March, 1897. The tumor removed was hardened and subjected to a careful microscopial examination by Dr. J. H. Wright, and was shown to be an adenocarcinoma.

I will at once state that up to this time (January, 1901,) there has been no sign of recurrence of the growth at its original site in the anterior rectal wall. The scar left by its removal is soft and covered by smooth mucous membrane.

Two months after the first operation a second operation was done for the closure of the posterior opening in the rectum. This was effected by refreshing the edges of the opening, and then closing it by layers of buried catgut stitches. The first row approximated the rectal wall, the second drew together the muscles and connective tissue posterior to the rectum, and a final row of silkworm gut stitches closed the skin. Healing occurred by first intention, and the patient remained well until the summer of 1899.

At this time his physician, Dr. E. H. Stevens, noticed a hardening of the tissues behind the rectum, and I was called and concurred in his belief that a recurrence of the disease had occurred in that situation. On July 14, 1899, I operated for the removal of the mass which was about as large as a hen's egg, flattened in the anteroposterior diameter and extended from the mucous membrane of the rectum, backward, along the sacrum to which it was firmly attached. This mass was cut out with a liberal margin of, seemingly, healthy tissue about it, including so much of the rectal wall as seemed to be attached to it. The mucosa, thus removed, looked healthy. The mass which was removed was sent to Dr. J. H. Wright for examination and his report was as follows:

The specimen consists of a mass of tissue of about the size of a mandarin orange. It is made up of muscle, fat, some bone and an irregular tumor, about the size of a pigeon's egg, to which at one point a small patch of rectal mucous membrane, about 1 c.m. in diameter, is adherent. On section, the tumor presents a fibrous, trabecular structure supporting a gelatinous, translucent material. Microscopial examination of a section of the tumor, about 23 mm. in greatest diameter, shows the following:

The main mass of the section is composed of a connective tissue stroma supporting tubules formed of columnar epithelium and small cystic structures lined, in many instances, with a single layer of columnar epithelium. In some instances the epithelium is absent. The cystic structures are regarded as dilated tubules. The largest of them is about 3 mm. in greatest diameter. Most of them, as well as some of the tubular structures, contain a reticulated coagulum which is evidently mucoid in character.

The tubular structures often appear to branch. The usual goblet cells, so characteristic of the mucous membrane of the rectum, are absent from the cells lining these tubules.

The small patch of rectal mucous membrane mentioned above is continuous with the atypical tissue just described, but no transition is apparent between the characteristic tubules of the rectal mucous membrane and the atypical tubules of the new growth, for at one point there is an abrupt change in the character of the tubules.

Diagnosis. — Adenocarcinoma with colloid degeneration.

Since this operation Dr. Stevens has, on two occasions, cut out little bits of hardened tissue in the scar. Microscopial examination in each case showed the bit removed to be only a mass of fibrous tissue. (Keloid.) The scar in which the recurrence took place was separated by an interval of 5 or 6 inches from the original seat of the growth, and the tissues between have remained wholly healthy. This is plainly, therefore, not a case of direct extension of the disease. The lymphatic vessels from the seat of the original disease run upward to the lumbar glands, not downward toward the point of recurrence. This anatomical relation, together with the absence of any lymphatic structure in the recurrent nodule remove any suspicion of this having been a secondary growth in a gland. We are then obliged to believe that this was, indeed, a case of transplantation of cancer. Certainly, the conditions were favorable for this happening as the cancer, torn and squeezed by forceps, was rubbed for several minutes into the fresh wound.

This experience emphasizes the importance of taking great care during the removal of a cancerous growth to go wide of the disease so as to avoid the possibility of inoculation. This is a precaution long observed by many surgeons, but, perhaps, not sufficiently dwelt upon in surgical teaching. It is interesting, also, to note in this case that the antiseptics used to cleanse this wound, which by its contiguity to the rectum was consciously infected, did not suffice to prevent the survival and growth of the cancer elements.

MASSACHUSETTS GENERAL HOSPITAL. CLINICAL MEETING OF THE MEDICAL BOARD.

REGULAR meeting, February 8, 1901, DR. C. B. PORTER in the chair.

DR. JAMES C. WHITE showed

A CASE OF ICHTHYOSIS IN A BOY FOUR YEARS OLD.

This is a very well developed case indeed, and it is interesting, by contrast with the other series of cases I shall show, as an affection of the epidermis and the papillary layers of the skin which begins in the first year or two of life, and remains permanently through life like those, becoming aggravated as years go on, but never undergoing any secondary changes. The other affection, xeroderma pigmentosum, begins at the same time in life, consists also of epidermal and pigmentary changes, and goes on to most disastrous results, as you know. You will please note the rough, harsh,

shagreen condition of the skin in the ichthyotic patient with the great formation of colored epidermis, an unusual feature in a child at this stage of development of the disease; also that the skin in flexures of the limbs remains normal.

CASES OF XERODERMA PIGMENTOSUM.

This first child is one of the two little sisters whom you have seen before. They have red hair and light eyes. The disease began with them, as is usual, within the first two years of life. This case has been operated upon many times for the removal of keratosic new growths and epitheliomatous transformations upon the face and hands. It is interesting now because she has had eight or ten exposures to Röentgen rays upon the central portion of the face, thus far without apparent effect. The other sister died last summer at Deer Island of the same affection, with tremendous carcinomatous destruction of the face. The hyperpigmentation extends all over the body, but the keratoses and the epitheliomatous transformations are confined to the face and hands in the survivor.

These other two cases of the affection I saw first fifteen years ago. They are dark brunettes of Northern Russia. When I saw this younger boy (now eighteen) he was two years old. The disease had begun with him a few months previously, consisting of very slight freckling. The elder brother, now thirty-two years old, was at that time a well marked example of the three primary changes, namely, the freckling, that is, the pigmentary hypertrophy, the telangiectalic new growth, and the atrophic condition of the skin. They were the only changes that this case had exhibited up to within a year, in which respect this is almost an unparalleled case. Now for the first time, within the last six months, there begins to develop the inevitable change of an epitheliomatous character in the form of a large fungating outgrowth on his side chest.

The younger brother has on his face here and there slight keratoses, but there has been as yet no epitheliomatous transformation, nor does he exhibit to so generalized a degree as his older brother the primary changes. For instance, the pigmentation does not extend below the nipple, whereas it is continuous over the other with much greater development of the telangiectalic new growths and of the atrophic condition which you see, especially on the face and ears.

I have asked these three cases to come in this evening because they illustrate, in the first place, an extraordinarily early development on the part of the little girls, the red-haired children, of the later destructive transformations with a fatal termination in one of them, and a rapid degeneration of tissue in the other, on the one hand, and in the case of the black ones how long they have resisted any tendency to the formation of keratoses and any secondary transformations. In the young man thirty-two years old it is almost unprecedented that the disease has gone so long without any such secondary tissue changes, for the disease does undergo this transformation in all cases, and a lethal termination is always present; in other words, the prognosis is inevitable.

Now, it seems to me that the progressive process in this affection is wholly militant against the opinion that carcinoma or epithelioma is a parasitic affection. If it be parasitic it is of extraneous origin, because these are not congenital cases, nor do we assume that any such forms of parasitic disease are ever congenital, born with the child that is, and yet we can predict absolutely that eventually these cases are going to develop epithelioma. Now, it is not according to the doctrine of chances that, if this be a parasitic affection, in every one of the hundred cases on record these germs from without are going to be present and strike them. On the other hand, we can predict absolutely that in the child with ichthyosis, which is a very common disease, comparatively speaking, with keratosic tissue changes of the skin there will never be any carcinomatous transformation.

MYXEDEMA.

Dr. R. H. Fitz showed a patient whose symptoms and signs were best explained by the diagnosis of myxedema, although in certain respects the course of the disease differs from the generally recognized characteristic features of this malady.

The patient is a shoemaker, forty-one years of age and unmarried. There is no venereal history, but he admits the frequent use of beer, sometimes in large quantities. Before the age of twelve, he had suffered from measles, variola and typhoid fever. Several ribs had been broken and abscesses had been formed in the right side of the neck. He is of powerful build, and has weighed 212 pounds. When twenty years old he could run 220 yards in twenty-five seconds without preparatory training.

Four years ago he noticed that he could no longer work at his trade as rapidly as before, and two years ago gave up his place on account of increasing sluggishness of action. His feet and hands were numb and his legs felt heavy. At this time his friends noticed that his face appeared swollen and his skin was rough. Although his movements were slow and his muscles were easily fatigued, his mind became excitable. He was sensitive to slight draughts of air and sweated easily. During the past eighteen months he has suffered a considerable loss of hair. His weight has diminished about 40 pounds during the past three years.

At present the face appears moderately swollen and its lineaments are largely obliterated. It is pale except over the cheek bones, where are persistent red patches, due to capillary and venous dilatation. The hair is thin and dry and the scalp is partly bald. The eyebrows are unaffected, but the axillary hairs are few. There are no supiaclavicular swellings but there are enlarged lymph-glands, some fluctuant in the right side of the neck. There is no appreciable alteration of the thyroid gland. The skin of the arms and legs is cool, dry and scaly, but the sweat gland in the

axillæ secrete freely. The nails of both fingers and toes are normal in appearance. The edge of the tongue is indented by the teeth, several of which, especially of the upper jaw, are lacking. The mind seems alert, but speech is slow and deliberate. The pulse is between 50 and 60 beats per minute and the temperature is subnormal. The urine contains a trace of albumin, and the examination of the blood shows a slight degree of anemia. The knee jerks are feeble, cutaneous sensibility is but little disturbed, and the difference between heat and cold is readily recognized.

Two days after his admission to the hospital he became so suspicious of his surroundings, that he left the ward at night and was found by the police wandering about in his night shirt. His delirium resembled that caused by alcohol.

Although the physiognomy of this patient, the sluggishness of speech and action, the loss of hair, the condition of the skin, the slow pulse and subnormal temperature, are indicative of myxedema, the condition of the mind, especially the active delusion and the sweating, is unusual. Despite these deviations from the type of the disease, the diagnosis is strengthened by the rapid improvement that is following the use of thyroid extract.

DR. ARTHUR T. CABOT showed the

PHOTOGRAPH OF AN ARTIFICIAL ANUS FOLLOWING A KRASKE'S OPERATION FOR CANCER OF THE RECTUM.

The patient, a middle-aged woman, had been operated upon a year ago for an extensive malignant tumor of the rectum. Five or six inches of the lower part of the bowel was removed, and the end was brought out at the side of the sacrum where the coccyx had been cut away. The patient now has almost perfect control of the bowels. The opening is small, just admitting the forefinger, and the finger introduced into this opening as it reaches the back of the uterus passes through a narrow place in the bowel and is grasped as by a sphincter. This narrow point is easily passed by the finger, but it seems as if some of the circular fibres of the bowel had taken on more or less sphincter action.

The case was introduced to show how satisfactory the final results accomplished by this operation may be. It might be expected, and is usually supposed, that an artificial opening of this sort would be extremely troublesome, but that it is not necessarily so, this case attests.

DR. ARTHUR T. CABOT reported an observation on the

INOCULATION OF CANCER IN A FRESH WOUND.[1]

DR. H. F. VICKERY showed a

CASE OF ELEPHANTIASIS.

The first case is one of elephantiasis of moderate degree in a mulatto woman who was born in South Carolina, and was seventeen years old when she entered the wards last September. She came in on account of symptoms which were easily explained by a marked chlorosis which she had, the hemoglobin being only 50% of normal; but the object of interest to us was her right leg, below the knee and including part of the foot. The leg was symmetrically enlarged; the hair follicles somewhat farther apart than on the normal leg, and the hairs rather more luxuriant. The enlargement was apparently due to hypertrophy of the skin and the subjacent connective tissue. The x-ray showed no difference in the bones. The case was seen by Dr. Bowen for the department of the skin, and Drs. Walton and Lord representing the nervous room. Dr. Bowen thought that it was a sort of elephantiasis. The nervous specialists did not think that it belonged in their department.

True elephantiasis of tropical origin is due to the presence of the filaria sanguinis nocturna, although the filaria cannot, as a rule, be found in the general circulation in these cases, being confined by the choking up of the lymph glands of the diseased part with the eggs of the filaria. Repeatedly the blood of this patient was examined day and night, both from the leg and from other parts, but no filaria was discovered. Different from ordinary elephantiasis, again, is the fact that she never had any erysipelatous attacks in the leg. This leg measured the same size as both her thighs, nearly 41 centimetres.

TRICHINOSIS.

I should like to speak briefly of 2 cases of trichinosis: 1 that occurred in my own service, and another later in that of Dr. Shattuck, which I report by his permission. The interest of my own case was the degree of fever, which reached 104° F., associated with a slow pulse and an enlarged spleen just as in typhoid. The pulse ranged from 100 to 105. This patient came in in typhoid fever times, the 6th of September. A man, twenty-two, born in Boston and fond of eating pork. The story was that two weeks before entrance he began to notice soreness in the muscles of the arm and leg so that it pained him to bend them; the joints were not affected. Soon he began to feel tired; sleep did him no good. Contrary to what might have been expected in trichinosis, there had been no vomiting or diarrhea. His face was somewhat puffy when he entered. The diagnosis was not made until the blood was examined, when the presence of an immense number of eosinophiles at once put us on the right track. A piece of the gastrocnemius being removed displayed the trichinæ, not calcified, lying in a somewhat inflamed tissue. The number of white cells at one count was 25,000, and of these 29% were eosinophiles compared with perhaps 2% to 4% as the normal maximum.

Dr. Shattuck's case of trichinosis was in a young woman from Ireland, twenty-three years old, who had only been in this country two and a half months. A week before entrance the muscles of the arms and legs became sore; there was no swelling or redness of joints; she felt weak; the bowels were constipated; she vomited every day.

[1] See page 471 of the Journal.

She had a moderate fever of about 102° F. and the same characteristic blood count. Trichinæ were found in the muscle. One thing was noticed in her case which is said to be characteristic of the disease, a marked variation in the number of eosinophiles. On the 17th of November there were 23%; on the 19th only 7%; on the 22d there were 37%. At the time when they were reduced to 7% the white corpuscles were also reduced in total number down to 10,000; so that if we are unfortunate enough to hit just a certain time, even with trichinosis present, there may be a very moderate eosinophilia. This case presented no enlargement of the spleen.

Dr. White: It seems to me, Mr. Chairman, that the first case is one rather of false than true elephantiasis due to the presence of filaria. The occurrence in the early stages of the latter of attacks of erysipelas-like dermatitis are almost constant, and I was not aware until the reader so stated that this filaria is found as far north as South Carolina. These sporadic cases which occur in northern regions are looked upon rather as non-parasitic, and are called false elephantiasis on that account, due to some condition of the lymph vessels, not a mechanical stoppage by the filaria, but to other processes which lead to precisely the same results.

Dr. J. W. Elliot demonstrated a

CASE OF STONE IN THE URETER LOCATED BY THE X-RAY.

The patient is a woman, married, thirty years old; had been operated on in 1898 by Dr. Harrington for gallstones; again in 1899 for stricture of the pylorus; and again for adhesions about the stomach. Sixteen days before entrance she had a severe attack of pain in the right kidney region extending down in the leg, requiring a grain of morphia. The next day she passed bright red blood in the urine. Since then several similar attacks of pain; with each attack bright red blood came in the urine. The urine showed a slight amount of albumin, was brownish in color; the sediment contained pus and blood. The attack she had here was very severe. She was evidently losing ground rapidly, and the operation was done at once in spite of her poor condition, on account of the collapse which was evidently due to some disturbance of the kidneys.

The x-ray showed a stone in the right ureter just above the crest of the ilium. It was a very useful shadow for the patient, in that, although I knew the stone must be in the ureter because the blood was so bright, yet I could not have located it at all; should have been obliged to strip up the ureter to find the stone, in fact, I could not have been sure it was not in the kidney. I found the stone exactly as it appeared in the skiagraph. I exposed the kidney and ureter by a curved incision in the loin, retracted the peritonium and the abdominal contents toward the median line. The ureter was seen much enlarged for a distance of two inches below the kidney. At the lower extremity of this enlargement I felt the stone and easily removed it, closing the ureter with several fine silk stitches. The stitches have held well, and there has been no leakage of urine through the wound.

According to Leonard, 6 cases of stone have been located in the ureter by the x-ray. He states that it is very valuable and very accurate when the proper technique is used, and that a negative shadow is also of great value, and, certainly, when I felt this stone, it was so exactly where the x-ray showed it, that I made very little further search, trusting to the x-ray, as it had been so plain and so accurate I did not put a sound down the ureter as I should otherwise have done. That saved getting urine into the wound. I did, however, feel of the kidney and pelvis of the kidney very carefully, because one naturally expects to find other stones in the kidney, but nothing was felt.

PROSTATECTOMY BY THE COMBINED METHOD. (ALEXANDER.)

These are fragments of a prostate from the prostatic urethra removed by a comparatively new method, the combined method, as described by Dr. Alexander, of New York. This was a chronic prostatic patient who was sixty-eight years old. He had had to pass his water four or five times at night for three or four years and came in with retention. Since his retention, has passed his water every half hour. On examination by rectum the enlarged prostate appeared to be rather low down, the disease seemed to be principally in the region of the prostatic urethra, there being no large lateral lobes extending up beside the bladder, so that I thought it was a case particularly adapted to this method. The method is that you open the bladder by a suprapubic opening, put one or two fingers in, push the prostate down, then you make a perineal opening, by an external urethrotomy, opening up to the prostate, lower end; then, by bearing one hand down from above, pass the other hand in through the perineal opening and begin to shell it out.

The urethral opening in the bladder was surrounded by a very thick, round, hard, raised ring, so that there was a deep "bas fond" of the bladder. Putting my hand inside to push that down I felt that the prostate was wholly in the prostatic urethra, and I shelled out first one side and then the other, and tore it away from the prostatic urethra without opening the bladder at all and without opening the prostatic urethra at all. At the end of the operation I felt satisfied that I had removed all of the prostate and that there could be no further obstruction to the flow of the urine.

Dr. Elliot, in answer to a question by Dr. Harrington in regard to his impression of the case or difficulty of the Alexander operation, said: "I got a favorable impression of the operation itself." Every one who has done the operation likes the mechanical part of it. The question is, whether the mortality will be high. Dr. Alexander has reported 32 cases with 3 deaths, I think. In one year I did 8 cases of suprapubic prosta-

tectomy with 1 death. But the Alexander operation seems to me a much better operation, much more complete. I felt I got all of the prostate out. In all those other operations done by the suprapubic method I could not get down into the prostatic urethra far enough so that I felt that I had cleaned out all the prostatic enlargement. In this case there was not a bit of the obstruction left anywhere. Dr. Alexander does the operation very quickly. It seems to me wise to take plenty of time as it is not a long operation. There was not much hemorrhage, no more than in the ordinary perineal section. What surprised me was, that I got out the entire prostate without opening the bladder. The prostatic urethra was not injured.

DR. ARTHUR T. CABOT said that in the only case of stone in the middle portion of the ureter for which he had operated, long before the x-rays were used for the detection of these calculi, the location of the stone was easily and exactly made out by the point of greatest tenderness. The patient in his case had suffered extremely from pain, having been kept under ether for twenty-four hours before Dr. Cabot saw him, with but short intervals of consciousness. He said that in that case he did not sew up the ureter and yet the wound healed quickly without trouble. He expressed a fear that in sewing up the ureter, especially when silk was used for that purpose, there was a danger, in case the slightest leakage of the urine occurred, that the stitches would act as a nucleus for stone formation, and considering the fact that longitudinal incisions in ducts of this sort heal readily without suturing, it seemed to him perhaps better not to apply stitches.

DR. ELLIOT: I did not intend to put any of my stitches into the mucous membrane of the ureter. The ureter was pretty thick and very easy to sew. I might have got some in, but did not intend to put them in.

One interesting thing in this plate was that when it was fresh you could see the shadow of the ureter for about an inch and a half above the stone and you could not see any other part of the ureter. I thought there might be a deposit of lime, but found none. I do not know now why there was a shadow of the ureter just above that.

DR. JACKSON exhibited some x-ray plates of multiple calculi of the right kindey. The patient, a man of twenty-five, had been operated on five years ago by Mr. Bennet, of London, and a large calculi removed from the right kidney, the nature of which is not known. Two years ago symptoms of calculus returned and an x-ray plate showed four stones very distinctly. From Professor Wood's analysis of the urine it was evident that a marked pyelitis was present, and it was decided that the calculi were in all probability made up of urates which would correspond with the results obtained by the x-ray. The case is interesting also on account of the good results obtained by medication. For a year the patient had diuretics of various kinds without any effect either on his symptoms or the calculi. He then took lycetol (Bayer), 5 grains 3 times a day for six months. Within three months the symptoms and pain had disappeared and the pyelitis had nearly cleared up. At the end of six months the x-ray showed that two stones had disappeared. The dose of lycetol was then diminished to 5 grains once a day, which was continued for about six months longer. The last x-ray plate showed a very faint shadow where one of the stones had been. The patient feels perfectly well and the urine is now practically normal.

(To be continued.)

Medical Progress.

REPORT ON PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

(Continued from No. 19, p. 454.)

THE ILEOCECAL ORIFICE AND ITS BEARING ON CHRONIC CONSTIPATION, WITH REPORT OF TWO CASES RELIEVED BY OPERATION.

WILLIAM J. MAYO[13] has operated upon 2 cases, excising a portion of the cecum, after the Heincke-Mikulicz pyloroplasty, making a considerable increase in the size of the aperture between the ileum and cecum. The literature bearing on this subject as to the function of the ileocecal valve is not large, and Mayo believes that one of the many functions of the ileocecal opening is to prevent the too rapid emptying of the small bowel and to maintain some pressure against peristalsis until the process of small bowel digestion is properly completed. His operation is a suggestive one, and it is possible that it might be practicable in selected cases.

RESULTS OF RADICAL OPERATION FOR CANCER OF THE RECTUM.

Kröchlein[14] has investigated a series of 881 cases of excision of the rectum in order to ascertain: (1) The rate of mortality; (2) the recurrence facts; (3) the functional result, incontinence. Eighty per cent. are reported curative. In 14% it is stated to be permanent. The best functional results are obtained when the resected gut is fixed at its normal site and the sphincter and anus are preserved. The perineal method is suitable in some cases. The sacral is best suited for high seated cancer.

Kraske states that he has obtained satisfactory results in 120 cases by the sacral method. Also that the combined abdominal sacral method is a more radical one. The abdomen is opened, the superior hemorrhoidal artery is tied in order to permit a bloodless section of the peritoneal cavity of the bowel. The mesocolon and mesorectum with their glands are removed. The usual sacral operation is then done.

Hochenegg emphasized the necessity of preservation of the sphincter if incontinence is to be avoided. He recommends denuding the retained

[13] Annals of Surgery, September, 1900, p. 364.
[14] Verhand. d. Deutsch. Gesellsch. f. Chir., xxix, Congress.

anal segment of its mucous membrane and anchoring the proximal segment of the bowel in its grasp.

Wölfler attributes the failure to avoid incontinence to the disturbed innervation of the tissues involved in the operation.

OMENTAL FIXATION FOR RELIEF OF ASCITES FROM HEPATIC CIRRHOSIS.

M. M. Kusnetzow has attempted to ascertain how far the blood circulation in the region of the portal vessels is improved by newly formed adhesion in the abdominal cavity and by omental fixation, and in what manner the portal vessels anastomose with the inferior vena cava. In dogs he found by injection the following anastomoses: (1) Numerous anastomoses between the veins of the stomach wall which empty into the superior gastric vein and those which empty into the large vein along the greater curvature; (2) a direct connection between the vena gastro duodenalis and duodeno-jejunalis. Also an anastomosis between these two and the portal vein trunk through the pancreatic veins; (3) anastomoses between the neighboring veins which on one side open into the large, on the other into the small mesenteric veins.

These anastomoses permit the passage of the blood in case of ligature of the portal vein from the portion below to that above a ligature of the portal vein.

In his experiments Kusnetzow fully ligated the peripheral branches of the portal vein: (1) The superior mesenteric vein; (2) the inferior mesenteric vein; (3) the different branches of the same simultaneously. Also he ligated the trunk of the portal vein either fully or so that its lumen was diminished one-half to one-third. Each dog was operated upon two to three times. At the first operation the abdomen was opened and the omental fixation made. At the second a mesenteric vein or the peripheral portion of the portal vein was ligated. At the third the main trunk of the portal vein near the liver was ligated. Of fifteen dogs one died. Some were killed and examined one to three months after the operation, and the injected veins examined. The conclusions formed from the conditions found have convinced Kusnetzow that the treatment of ascites due to impeded portal circulation by omental fixation can give good results: (1) That Talma's operation is preferable to De la gé mèrés since it gives better conditions for the collateral circulation; (2) that without previous omental fixation complete ligation of the portal vein rapidly causes death; (3) that omental fixation enables animals to bear a double ligation of the portal vein; namely, a complete one in its middle part (above the entrance of the gastrolienalis) and an incomplete one near its entrance to the liver; (4) complete ligation below the vena gastrolienalis caused death in a few hours even after previous omental fixation; (5) the incomplete ligation of the portal vein in its middle portion caused stasis ascites and bloody diarrhea which was transitory as in 3; (6) the superficial epigastric veins dilate markedly after omental fixation resembling the "caput medusæ" seen with hepatic cirrhosis.

Also the veins of the great omentum soon communicate with the veins of the abdominal wall and the superficial epigastric vessels. Then the blood flows from the portal vein through the gastrolienalis into the omental veins, then into the epigastrics, the femorals, intercostals and mammary vessels. Also a direct anastomosis between the portal system and the inferior vena cava is formed by the dilatation of previously existing very small vessels showing that there is normally a slight communication between the portal system and the vena cava as Sappy has stated. This is best shown by injecting the vena cava and the portal vein with different colored injection. Adhesions and connective tissue bands formed in the abdomen after laparotomies contain many small vessels which can serve to form anastomoses between the vena cava and the portal vein. In case of ligature of the portal vein one should consider the normal anastomoses between the different branches of the portal vein which facilitate the formation of new blood channels. The details of the experiments are not given in the report at hand,[15] which is a preliminary one.

It is unfortunately not stated if the above conclusions are based on the venous anatomy of dogs or in the human venous system. Further reports on this subject will be awaited with interest.

WHEN SHALL WE OPERATE IN CHOLELITHIASIS?

Kocher,[16] in answering this question, says: The indication is given by the recurrence of gallstone colic attacks, which show the presence of multiple calculi or of one that is so large that it cannot pass through the bile ducts, or can do so only with great injury to them, or, finally, where a newly-formed calculus is passed. When any of these indications are present we should not wait until secondary changes have occurred, and inflammation, with its sequelæ and even perforation, may have taken place, or malignant degeneration has occcurred; then recovery is seldom seen.

Is intervention indicated in cases where recovery from the attack is probable and there are no complications? He believes that operation gives the best chance, and is indicated. Simple cholecystotomy is rapidly recovered from, and with perfect technique there is no great danger, and not nearly as much as from the complications that arise from a further development of the disease or the presence of infection. The early operation may remove a great number of calculi, and the ten days required for operation and recovery are well spared when compared with the consequences of repeated attacks.

The ideal cholecystotomy consists in exposing the gall bladder, opening it, and removing all calculi. It should then be immediately sutured and returned to the abdomen. Such an operation requires absolute asepsis and a perfect suture. The

[15] Contrbl. f. Chir., 1901, Bd. xxviii, S. 105.
[16] Correspondenzbl. f. Schweiz. Aertze, April 1, 1900; American Journal of the Medical Sciences, August, 1900.

best suture this author believes to be silk. It is inserted only in the wall of the bladder and does not enter the cavity, so the danger of its forming nuclei for other calculi is entirely avoided.

Kocher has performed this operation six times during the winter semester. All the patients recovered, without rise of temperature, in eight days, and were sent home in two weeks' time. This illustrates the simplicity of operation at this early period as soon as the diagnosis is established and before complications have rendered the intervention more hazardous.

He does not believe that any form of medical treatment can remove these calculi or prevent the patient from having recurrent attacks until the calculi are removed. Recurrence is not probable after all the calculi are removed, but the patient should be put upon a regulated diet, with the end in view of preventing the formation of other calculi.

OPERATIVE TREATMENT OF ACUTE HEMORRHAGIC PANCREATITIS.

Hahn[17] rejects in all cases where this lesion is the probable diagnosis the present commonly employed "symptomatic" and "expectant" treatment. Also all radical, extensive or severe operative treatment. He recommends only a small incision below the navel in the median line to remove the exudation and for drainage.

He gives as characteristic symptoms the sudden, unusually severe epigastric pain, violent eructations, biliary vomiting, constipation, distension, especially epigastric, tenderness, severe collapse, (cool extremities, face, etc.), subnormal temperature, pulse increased even to 160. Death in four or five days. In all his cases these symptoms were more or less pronounced.

PANCREATIC SURGERY.

Ceccherelli[18] summarizes his views on pancreatic surgery under the following headings:

(1) Surgical operations on the pancreas are involved directly in all the questions regarding the functions of this gland.

(2) The loss of flesh, the presence of fat in the feces, sugar in the urine, bronze discoloration of the skin, icterus and pains, are the symptoms which accompany the majority of pancreatic disorders.

(3) Considerable difficulty is encountered in performing complete extirpation. The anatomical conditions are unfavorable; the organ is deeply situated and intimately connected to other viscera. It is very rich in blood vessels and nerves, and secretes an important digestive ferment.

(4) The surgery of the pancreas has not kept pace with the advance in other fields of abdominal surgery. The diagnosis of these conditions is difficult, and is generally arrived at too late for successful operation. It has been shown, however, that operations on the extremity of the pancreas are more often indicated than upon the head.

(5) Although experimentation has shown that animals live after complete extirpation, clinical experience has not as yet confirmed this result. Cases are usually malignant and die from the disease before the effect of the operation in removing the pancreas can be noted. In other conditions partial operations are indicated, and should leave behind one of the canals if its outlet can be preserved.

(6) The tumors most frequently found in the pancreas are cystic, hematic due to traumatism or apoplexy, or retention or hydatid cysts. In these cases intervention is justifiable, but removal of the sac is all that is necessary. In operating, if possible, the wall of the sac should be sutured into the abdominal wound, or, if impossible, the suturing of the cavity should preclude infection of the peritoneum.

(7) Calculi of the pancreas can be readily extracted.

(8) In necrosis the necrosed portion should be removed.

(9) In suppurative or gangrenous pancreatitis the acute period should be left alone. In case of abscess of the pancreas the entrance can be either lumbar, extraperitoneal, or transpleural, or through the median line above the umbilicus. It is sometimes necessary to remove a portion of the necrosed pancreas.

(10) Chronic pancreatitis may constrict the ductus choledochus or the pylorus. The operation is then not on the pancreas, but to relieve the constrictions.

(11) Herniæ and wounds are treated on general principles. A displaced pancreas may be sutured in position. Injuries of the ducts or their occlusion may require the formation of a new duct or a pancreatic fistula.

(12) Sutures through the substance of the pancreas do not interfere with its function. In suturing the canals the sutures should be close together and should not enter its lumen.

(13) In removing the pancreas the ligatures should be applied before the incisions are made, to prevent hemorrhage.

(To be continued.)

Recent Literature.

Tuberculosis as a Disease of the Masses and How to Combat It. By S. A. KNOPF, M.D. New York: M. Firestack. 1901.

IN presenting to the public the translation of his prize essay upon "Tuberculosis as a Disease of the Masses and How to Combat It," written for the Berlin International Congress in May, 1899, Doctor Knopf has added another valuable work to the literature upon the subject.

With a full knowledge of the subject, especially of the sanatorium treatment of phthisis, he has succeeded in making a concise, yet thorough work, which is instructive not only to the practising physician but to the laity as well.

The fact that the essay was awarded the prize among eighty-one competitors, after three trials, the judgment being given finally by Doctors Fränkel, Gerhardt, Harms, Köhler and Pannwitz, would in itself speak for the value of the work. The reader will, we believe, think this decision justified.

In his "Preface to the English Translation," the author speaks of certain necessary changes which have to be made in his suggestions to suit the different social conditions existing in Germany and America. He cites the fact that while in Germany every laboring man and woman must be insured against old age, accident and disease, including tuberculosis, and the employer is held responsible for compliance with this law, no such law exists in America, where no insurance company will insure a tuberculous person.

In America, moreover, each State has its own sanitary laws, while in Germany there is one homogeneous law for the whole country, a national institution, which is a consummation devoutly to be wished for in the United States.

It would be impossible here to review in detail the different chapters. Suffice it to say that the author, while believing thoroughly in the communicability of the disease, yet holds a conservative and rational view of the dangers of infection where certain simple, but rigid precautions are taken.

There are excellent words of advice in the matter of hygiene, methods of dress, gymnastics, etc.

The author touches but lightly in this work upon the subject of sanatorium treatment, having gone exhaustively into these matters in previous works, but gives a few short, well-illustrated chapters of the steady growth of this modern method of treatment, and also of the comparatively simple methods of fresh air treatment in the homes of the poor when removal to a sanatorium is impossible.

Doctor Knopf has on many occasions strongly emphasized the necessity of model tenement houses for poor people and of the importance of legislation preventing the erection of any unsanitary buildings for this purpose. In this work he also emphasizes these ideas in connection with the suggestions for the establishment of various kinds of institutions for the reception of tuberculous patients.

In his closing chapter the author speaks of these suggestions as follows: (1) Centrally located reception hospitals and dispensaries for the treatment of ambulant tuberculous patients whose admission to a sanatorium is impracticable for any cause; (2) one or several city sanatoria located in the outskirts where purer air can be obtained as a temporary sojourn for patients before being sent to a mountain sanatorium and where advanced cases could be retained; (3) one or more mountain sanatoria for the incipient cases; (4) seaside sanatoria for children with scrofulous or tuberculous tendencies; (5) maternity sanatoria where tuberculous mothers could be instructed in matters of hygiene for themselves and their children.

The essay has several excellent illustrations and will make a valuable addition to any physician's library.

Chronic Urethritis of Gonococcic Origin. By J. DE KEERSMAECKER, Chief of Service, Diseases of the Urinary Organs at the Centraalklinik, of Antwerp, and J. VERHOOGEN, Agrégé at the University of Brussels; Chief of Service, Diseases of the Urinary Organs at the Polyclinique Libre. Translated and edited, with notes, by LUDWIG WEISS, M.D., Attending Physician to the Genito-Urinary and Skin Service, German Poliklinik; Dermatologist to the Hebrew Orphan Asylum, New York, etc. New York: William Wood & Co. 1901.

This is a book of 251 pages and a sufficient index. The pages contain a good many conventional illustrations, chiefly of the instruments used in the treatment of chronic urethritis, and they also contain 15 colored figures illustrating normal and pathological conditions of the male urethra as seen through the endoscopic tube. Oberlænder's preface to the original edition of the book (1897) as well as the translator's short preface to the present volume precedes the text proper, which is divided into three parts. The first of these is devoted to the anatomy and pathology of the male urethra, the second to diagnosis, and the third to the treatment of the disease to which the book is for the most part devoted.

The volume is a very complete résumé of our present-day knowledge of the diagnosis and treatment of chronic gonorrheal urethritis in the male. It is very clearly and carefully written, and the completeness with which each little detail of treatment is considered, makes the book of real practical value to any one who wishes to embark upon a study of this disease. With the editor's motive in translating the book we cannot, however, feel in sympathy. He says in his preface that "he feels that his attempt to make urethroscopy available to the general practitioner, and acquaint his American confères with so useful a department of our science, may not be in vain." If our experience counts for anything, a little knowledge of urethroscopy is indeed a dangerous thing. A proper skill in the use of the urethroscope is to be obtained only by those who have constant and exceptional opportunities for acquainting themselves with it and with the disease in the diagnosis and treatment of which it can be so useful. Such opportunities, and the leisure to take advantage of them, must rarely present themselves to the general practitioner of medicine, and the wisdom of encouraging him to acquire an inadequate knowledge of and skill in the use of the urethroscope, may very properly be questioned.

Towards the end of the volume the editor has added a chapter entitled Chronic Gonorrhea and Marriage, in which he takes sides with those who believe that the gonococcus is the sole responsible cause of the disease. He concludes the chapter as follows: "We take the stand that we will give permission to marry to those having had gonor-

rhea, when, after repeated and careful microscopic examinations of slide specimens and exhaustive bacteriologic and microscopic investigation of the threads and the secretions of the prostate and seminal vesicles, done under the strictest rules and with the aid of Gram's method, the presence of gonococci cannot be demonstrated."

The History of Medicine in the United States. A collection of facts and documents relating to the history of medical science in this country, from the earliest English colonization to the year 1800; with a supplemental chapter on the discovery of anesthesia. By FRANCIS RANDOLPH PACKARD, M.D. Octavo, 526 pp. Philadelphia and London: J. B. Lippincott Company. 1901.

This is a timely and acceptable book. The author, as he states in the preface, has produced a work which has occupied many years in preparation, and has "truly been a labor of love." The interest it will arouse may not be general, but it will, most certainly, appeal to that growing body of physicians who are interested in the history of the development of their profession. At this period of the somewhat endless multiplication of medical books on so-called practical branches of medicine, it is a pleasure to take up a book which apparently has been written for no ulterior end.

The author has traced the history of medicine in America from the earliest days of English colonization down to the year 1800, with a supplementary chapter on the discovery of anesthesia. The task has, no doubt, been a difficult one, and the author has done well to draw liberally in the way of quotations on various original sources, supplying himself an explanatory commentary. This method gives a certain quaintness to the text, and detracts nothing from the clearness of the exposition. An added interest is given by numerous illustrations, chiefly of physicians of distinction who made the history of medicine in the eighteenth century.

Although the author makes no mention of his intentions for the future, we trust he will see fit to supplement this admirable volume by another which will cover the vast development of medical science in the nineteenth century. The historical retrospect should not be lacking, now that a new century is fairly started on its way.

The book is appropriately bound and excellently printed, and contains a list of the chief authorities consulted and a good index. The volume is most creditable, both to author and publisher.

BIRTHS AND DEATHS IN PHILADELPHIA. — It is stated that a recent report to the Philadelphia Board of Health showed that in the preceding week and in the last year there were more deaths than births in the city. During the week it is reported that there were 413 births and 565 deaths, and during the last year 10,013 births and 10,510 deaths.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 16, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ANOTHER ALLEGED CAUSE OF CANCER.

THE recent announcement, widely heralded in the newspapers, that the cause of cancer has been discovered to be a protozoon, as the result of work done in the New York State Pathological Laboratory, has attracted the attention of medical men on account of the high character of that institution.

The official statement concerning this work, published by the Director of the Laboratory as a leading article in the May number ef the *American Journal of Medical Sciences*, offers us an opportunity of estimating the merits of this alleged discovery.

We have read and reread this article with painstaking care and attention. We find the matter illogically and disconnectedly arranged, and the text abounding in paragraphs in which observation, inference and unjustified assumption are confused to such an extent as to render a scientific analysis difficult. The article shows a lack of that objectiveness which we look for in a scientific paper and a tendency to make facts harmonize with theory.

The author states that he has found large numbers of parasites which he calls protozoa in "all the organs, including the blood taken from all regions of all cases dying of cancer, including sarcoma and epithelioma," and also in the peritoneal fluid, in the organs and the blood of animals injected with carcinomatous material. He claims that he has seen this organism project pseudo-podia, and he has satisfied himself that it goes through a life cycle which ends with the formation of a sac-like body containing granules which he regards as spores. He also claims that he has found what he regards as the younger forms of these organisms in the peripheral blood in all cases of carcinoma and sarcoma examined by him in which cachexia was well marked.

We have carefully searched through this publication for some refutation of the obvious objection that the objects seen by the author and regarded by him as parasites are not simply more or less degenerated cells and products of cell degeneration, but we have found nothing that is satisfactory. The only objective evidence offered upon this point is the statement made in several places that the bodies are not fat, because they fail to give the reaction to fat. Another objection to the correctness of these results is the lack of proof by cultures.

Although the fact of cultivation of these hypothetical organisms is of the greatest importance for the justification of the author's belief that he has to deal with a parasite, he witholds, apparently, for a later publication, the description of the results of his culture experiments, merely offering the statements that he has succeeded in cultivating them "with comparative regularity, directly from cancer, from fluids which were in contact with cancer and from experimental animals," and that "the medium which has thus far given us the best results is that recommended by Celli for the cultivation of amœbæ, fucus crispus bouillon." Until some objective description of the results of these culture experiments is at hand we decline to assign any value to these statements in their bearing upon the question of parasites in carcinoma.

In brief, we cannot accept the conclusions and views of the author as above outlined; indeed, unsupported as they are by anything else than subjective evidence, they seem to us to be unworthy of serious consideration.

The reported results of the injection of a number of animals in various ways "with peritoneal fluid from cases of abdominal carcinosis, fluid from the interior of malignant ovarian cysts, sterile cancer, and dried sterile cancer and lymph-nodes rubbed up with salt solution," as also with what the author calls *pure cultures* of the organism, challenge attention.

That the author means by the term "culture" in this connection a growth of his assumed organism on a medium outside of the animal body is open to doubt, as will be apparent from the following quotation: "It will be shown from these experiments that animals are readily infected when inoculated with carcinomatous material, as well as *pure cultures* of the organism. The peritoneal fluid used in all of these inoculations was bacteriologically sterile and consisted essentially of a *pure culture*[1] of the organism." This statement clearly means that cultures in the usual sense of the term were not used for the inoculation of any of the animals.

[1] The italics are ours.

It appears that of the experimental animals, of which there were a considerable number, all, with the exception of one or two which were killed purposely, died after a variable length of time, often weeks and months, with emaciation, enlargement of the peritoneal lymphatic glands and of the spleen, and a small amount of fluid in the peritoneal cavity. Among these animals were three guinea pigs and two rabbits, which had been injected in the jugular with carcinomatous peritoneal fluid, and in whose lungs were minute disseminated tumors which the author found on microscopical examination to be multiple beginning foci of adeno-carcinoma. Also a dog, similarly treated, was found to present a lipoma of the spleen the size of a hazel nut, while one guinea pig, in the author's words, "presents a condition of the lungs and liver which I wish to interpret as primary carcinoma of those organs." Whether this last-mentioned guinea pig is one of the three guinea pigs previously mentioned, the author does not make clear.

These observations of a tumor formation in five or six of the experimental animals are important, if true. In only one of the animals are the microscopical appearances of the tumors objectively described. In this animal, from the author's description and from the photographs, we are convinced that true adenomatous neoplasms were present in the lungs. As to the nature of the conditions in the other four or five animals, we have only the author's interpretation and judgment. Because the contents of the paper as a whole do not inspire us with confidence in the author's interpretation of histological facts, we cannot accept his judgment on these cases of tumor formations as true without further objective statements.

If we believe that the author is not mistaken in his diagnosis of the conditions in these four or five animals, we must consider these tumor formations to be the result of the injection of the carcinomatous material, for the number of instances is then too large for their presence to be explained as the result of coincidence or spontaneous development. We thus arrive at a result which is altogether at variance with the results of trustworthy workers who have experimented upon animals with material derived from malignant disease in man.

The effects reported of the other experimental animals are of interest as indicating the poisonous character of the material injected into them, but they do not show that they are due to a parasite in this material, for, as before stated, we cannot accept the author's conclusions that he has seen parasites in the tissues and body fluids of these animals.

In our opinion, the publication of this article is to be regretted, not only because it will tend to spread through the profession and the community

ideas concerning the nature of cancer which are not supported by facts, but also because the palpable technical defects of the article will tend to bring scientific medicine in America into disrepute.

A MUNICIPAL HOSPITAL FOR PULMONARY TUBERCULOSIS.

A PUBLIC hearing before the Joint Committee upon Finance of the Boston Board of Aldermen and the Common Council upon the question of the construction of a Municipal Hospital for Consumptives, held at the aldermanic chamber last Tuesday evening, brought forth evidence of deep interest in this community in regard to this important matter. No less than eighteen physicians and laymen appeared and spoke in behalf of municipal care of consumptives in the city of Boston.

The first speaker, Dr. F. I. Knight, explained in a general way the needs which exist of a hospital for patients suffering from tuberculosis, outlined the scope of its possible usefulness and emphasized the large percentage of deaths due to consumption. He was followed by Dr. V. Y. Bowditch, who described the methods employed at the State Hospital at Rutland, and offered to the committee suggestions as to the probable expense of a municipal hospital adapted to similar purposes in the city of Boston. He especially advocated provision for chronic cases.

Dr. A. K. Stone heartily favored hospital treatment for tuberculosis on the grounds that such treatment enables the patient to be much better cared for than he can be in his own home, that his removal from home permits possible wage-earners in his family who are hindered from securing a livelihood by their necessitated attendance upon him, to earn their living and so to avoid pauperism, and, finally, because the segregation of the infected individual tends to prevent the spread of the disease by contagion.

Dr. Robert B. Howard advocated other provisions for the treatment of advanced cases than now exist, on account of the fact that many persons suffering from tuberculosis find it a great hardship to enter the charitable institutions, which, alone, among the hospitals at the present time, receive such cases.

In speaking of the expense of construction, Dr. Howard expressed the opinion that a hospital within the fire limits would cost about $2,000 a bed; buildings could, in his judgment, be erected outside the limits for a much less outlay.

Mr. J. H. Gallivan, street commissioner, who was interested in the founding of the Rutland Hospital, referred to the overcrowded condition of that institution and to the impossibility of its caring for any considerable proportion of the cases of tuberculosis now existing in Boston. He warmly supported any project in the direction of a municipal institution for the treatment of consumption.

The next speaker, Dr. W. H. Prescott, referred to his experience with tuberculosis in Boston in connection with work upon a Dispensary District, and at the Long Island and the Deer Island Hospitals. He has observed that tuberculous patients in the last two mentioned institutions do well in spite of their proximity to salt water. He believed, both from a medical and from an economical standpoint, that some plan should be formulated whereby consumptives may have an asyulm.

Dr. T. J. Reardon referred to the great prevalence of tuberculosis in Boston and to the decimation of families which it has effected, expressing the belief that our climatic conditions favor the spread of the disease.

Dr. H. C. Ernst favored the attempt to provide for the needs of tuberculous patients among the poor of the city, and suggested as a possible and suitable location for a hospital a tract of land in Jamaica Plain, overlooking the Arnold Arboretum.

In behalf of educational methods in the treatment of tuberculosis, Dr. Agnes E. Vietor, advocated small hospitals in various parts of the city which might stand in the same relation to the special hygiene of tuberculosis that the municipal bathhouses hold to general hygiene.

Dr. George Burgess McGrath spoke briefly of the work done by the Long Island Hospital in the care and treatment of tuberculosis, and of the results which have been obtained by the methods there employed. This hospital, which is upon one of the larger islands in the harbor, is one of the few institutions in which tuberculosis is treated at practically sea-level and in close proximity to salt water. The patients of this hospital have the advantages of about a square mile of territory, including nearly three miles of sea-beach, abundance of fresh air and sunshine, immunity from dust, and a geographical position which affords an attractive outlook and many means of diversion. Notwithstanding the hitherto inadequate parietal resources of the institution, 23% of the 160 cases of phthisis treated in the hospital during the year ending April first were discharged "well" or with the disease "arrested."

Dr. E. O. Otis, urged that the poor of our city should be protected from tuberculosis, and emphasized the fact that at the present time there is no municipal institution in which they may obtain treatment for the disease without receiving the stigma of pauperism.

Drs. Donoghue, Allen, Badger and Perry followed Dr. Otis, each giving some account of his

own experience with tuberculosis in connection with his Dispensary District work.

The Rev. Mr. George, of South Boston, the last speaker, strongly advocated tenement-house improvement and emphasized the crying need of better sanitation and hygiene in the homes of the poorer classes.

Councilman O'Toole then summed up the case for the petitioners, and the hearing was declared closed, the committee taking the matter under advisement.

This question of sanitoria and hospitals for those afflicted with pulmonary tuberculosis, is demanding constant and increasing attention, and we shall have to revert to it not infrequently — doubtless in connection with this very petition. Assent to the general proposition involved is more easy than agreement upon the details for its practical application.

MEDICAL NOTES.

A Field Hospital at the Pan-American Exposition. — Captain Edward L. Munson, U. S. A., has been selected to represent the medical department of the Army at the Pan-American Exposition at Buffalo. He will have charge of an exhibit consisting of a model field hospital, and will be in command of a detachment of thirty soldiers, who will give daily demonstrations of transportation of wounded, first aid on the firing line and field surgery, and the establishment and management of field hospitals.

Mississippi Valley Medical Association. — It is announced that the dates of the next meeting of the Mississippi Valley Medical Association have been changed from the 10th, 11th and 12th of September, to the 12th, 13th and 14th of September. This change has been made necessary because the dates first selected conflicted with another large association meeting at the same place.

Proposed State Sanatorium for Tuberculosis in Minnesota. — The Minnesota Legislature has established a commission to report concerning the advisability of a State Sanatorium for Consumptives.

Meeting of the American Medical Editors' Association. — The annual business meeting of the American Medical Editors' Association will be held in St. Paul, Monday, June 3, 1901.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, May 15, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 80, scarlatina 31, measles 139, typhoid fever 7.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending May 11th was 238, as against 203 the corresponding week last year, showing an increase of 35 deaths, and making the death rate for the week 22.1. Consumption 24, pneumonia 36, whooping cough, 0, heart disease 22, bronchitis 10, marasmus 3. There were 11 deaths from violent causes.

Further Opposition to Christian Science. — The elderly man who has been living during the winter in a tent in an outlying portion of Boston, presumably for the treatment of tuberculosis, is said to be gaining adherents to his doctrines, whatever these may be. If the following statement from a daily paper be true, they are, at least, sound in certain details: "At the same time with consumptives he wishes to treat people suffering from any disease which Christian Science has tried to cure and failed. He will take any such case — providing it is not surgical or contagious — and produce, by purely scientific methods, the same results that Christian Science sometimes produces; in other words, he will cure without medicine and without faith. He believes that Christian Science is spreading too rapidly, not only in this country but also abroad, and that its influence is pernicious, particularly in the disregard of contagious disease and the blessings of antitoxin which it teaches. Therefore, he says that he wishes to disprove its theories by cold scientific proof."

Worcester, Mass., Mortality Report. — The mortality report of Worcester, for March, 1901, gives the number of deaths, 189, as against 169 for March, 1900. It is of interest to note that 50 deaths, or 26.45% of the whole number were caused by pneumonia.

Pathologist to the Carney Hospital. — We understand the position of pathologist to the Carney Hospital is now vacant.

NEW YORK.

Law Regarding Disposal of Garbage Unconstitutional. — On May 10th the Appellate Division of the Supreme Court, in a suit brought by the Sanitary Utilization Company, upheld a judgment of the special term which declared unconstitutional the law which was passed by the legislature in April, 1900, without the acceptance of the city, amending Section 1,212 of the Greater New York charter. The section, as amended, made it unlawful to carry on, in Manhattan Borough, "bone boiling, bone burning, bone grinding, horse skinning, cow skinning, or the skinning of dead animals, or the boiling of offal," and made it also unlawful to carry on in the borough of Brooklyn the "rendering or treat-

ing with steam or boiling of garbage, swill or offal." It furthermore made it the duty of the Board of Health to cause the discontinuance of such business. The action was brought to restrain the Health Department from taking any steps to enforce against the company any of these provisions. The site of the company's plant on Barren Island was selected by the late Col. George E. Waring, Jr., when street cleaning commissioner, and the expense of erecting buildings and appliances was over $500,000. Within three months after the expiration of the contract then made, the city, by its terms, may acquire the plant at a price fixed by appraisal. The amount of garbage disposed of under the contract is stated by the company to be 900 tons a day during the year, and amounted to over 1,500 tons a day during the summer months. The case was before the court on demurrer to the complaint, and the judgment below sustaining the demurrer is now upheld.

MEDICAL SOCIETY OF THE STATE OF NEW YORK. — At the ninety-fifth annual session of the Medical Society of the State of New York, held at Albany, N. Y., January 29, 30 and 31, 1901, it was moved and unanimously adopted that, in order to increase the facilities for becoming permanent members of the society, each county society should be allowed to send five times the number of delegates it had formerly sent to the State society. These delegates are elected for a term of three years, and are eligible for permanent membership if they register twice during that time. This will make the number of delegates from county societies 750 in all, or one delegate for every eight or nine members of county societies, without increase of expense to the county societies. It was further agreed, in response to a widely expressed desire, that the society hold a semi-annual meeting in the city of New York in the early autumn, to be devoted entirely to scientific work and social intercourse.

MORTALITY STATISTICS OF NEW YORK. — The mortality of the city reported for the month of April represents an annual death rate of 20.67, against 21.39 in March and 24.26 in April of last year. As compared with March, the weekly average of deaths from pneumonia declined from 201 to 166.75; from influenza, from 27 to 17.5; from phthisis, from 179.75 to 177.5; from bronchitis, from 49.5 to 42.25; from diseases of the urinary system, from 129.25 to 124; and from diphtheria and croup, from 52 to 49.5. The weekly average of deaths from cancer increased from 48.5 to 51.25; from typhoid fever, from 9.5 to 11.25; from whooping cough, from 4.25 to 5.5; from scarlet fever, from 34.75 to 43.75; from measles, from 6.5 to 8.75; and from smallpox, from 8 to 9.25.

RESIGNATION OF DR. ROGER S. TRACY. — Dr. Roger S. Tracy, who has been in the service of the Board of Health for nearly thirty-one years, and who built up the system of recording vital statistics now in vogue and which has been followed by other cities here and abroad, resigned from the department on May 1st. He was first appointed registrar of records under the presidency of J. C. Bayles, and retained the position until 1892. From 1892 to 1895 he served as deputy registrar, and was then made registrar again. Dr. Tracy, in addition to numerous contributions to scientific publications, has written a work on "Physiology and Hygiene," and a "Handbook of Sanitary Information for Householders." He expects to travel for a time and to devote himself to literary work.

ACTION AGAINST CHRISTIAN SCIENTISTS. — The New Jersey Grand Council of the Royal Arcanum, representing 117 chapters in the State, in session at Trenton on May 7th, adopted a resolution to the effect that all persons who, when ill, reject, refuse or neglect the aid of medical science, are a very dangerous risk from an insurance standpoint, and that hereafter they shall not be eligible to membership in the order, unless agreeing or contracting to obtain or submit to such aid when ill, under penalty of forfeiture of insurance.

USE OF INTOXICANTS NOT A REASON FOR REFUSING LETTERS OF ADMINISTRATION. — Surrogate Petty, of Suffolk County, N. Y., has recently decided that the fact that a woman who has for some years been at times addicted to the excessive use of intoxicating liquors, is not a sufficient reason to refuse her letters of administration on the estate of her husband. In the case in which the decision was rendered, the application for letters of administration was opposed by the three adult children of the deceased.

SPREAD OF SMALLPOX. — In the first six days of May 135 cases of smallpox were reported, while during the entire month of April the number of cases amounted to but 199. The disease seems to be now well disseminated in all the boroughs of the city. On May 9th a policeman was attacked by smallpox and, on account of this, an order was issued by the head of the department that the entire police force should at once be vaccinated.

BEQUESTS TO HOSPITALS — Under the will of the late Joel Friedman the Montefiore Hospital for Chronic Diseases receives a bequest of $1,500 and the Mount Sinai and Beth Israel Hospitals each $1,000.

DECISION AGAINST NEW YORK UNIVERSITY. — One step in the litigation which has been in progress for years between the New York University

and the medical collage laboratory and the Loomis Laboratory has been terminated. Judge Truax of the Supreme Court gave decisions by which the medical school property on East Twenty-Sixth Street and its contents, valued at $150,000, is to be transferred by the New York University back to the medical college laboratory.

APPOINTMENT OF DR. L. EMMETT HOLT. — At the monthly meeting of the Trustees of Columbia University, held May 6th, Dr. L. Emmett Holt was appointed Clinical Professor of the Diseases of Children in the Medical Department.

AN EMERGENCY HOSPITAL ESTABLISHED BY WOMEN. — On May 5th, an Emergency Hospital established by women, with twenty-five beds and a well-equipped operating room, was opened in the old Gardner mansion at Union Hill, N. J.

BEQUEST TO FOUNDLING ASYLUM. — Among the charitable bequests of the late Mrs. Nathalie Reynal is one of $5,000 to the New York Foundling Asylum.

Correspondence.

SHALL IT BE SUNLIGHT OR SLEEP FOR CHILDREN? WHICH IS THE MORE EFFECTIVE AGENT FOR GENERAL HEALTH?

BOSTON, May 1, 1901.

MR. EDITOR: — I have recently passed through an experience that may prove of some value in answering the above questions. You know how prevalent the opinion is among those who have the means to enable them to take the best care of their children, that they should be put to bed in the middle of the day and sleep an hour or two. We have tried most thoroughly this system with our two children, continuing it until they arrived at the ages of two and one-half and three and three-quarters, respectively. They were very healthy children naturally, but we were constantly obliged to have medical attendance for them, and at one time they had serious difficulty with their ears, requiring surgical operations. Although they slept an hour or two, it kept them in-doors the best portion of the day. Between dressing and undressing, lunch and sleeping, there were six months in the year when they got, practically, very little sunlight, and what they did get was of very little consequence, it being so early in the morning or so late in the afternoon.

About six months ago we ceased putting them to bed and let them play out-doors all day long, and immediately we saw an improvement. Since then they have constantly gained until now they are as robust as any children could well be. Although one swallow does not make a summer, two swallows are twice as near to it, and our experience with these two children seems to me to go far towards proving that sunlight is one of the most effective agents for preserving the health of any living creature.

Nobody can over-estimate the value to health of sleep, but does the child get more sleep in the twenty-four hours by being put to sleep in the middle of the day? Our experience proved to us that this was not the case. For though our children slept an hour and a half during the day, they lost from one-half to three-quarters of an hour in getting to sleep in the evening, and woke an hour earlier than now in the morning.

Very truly yours,

E. G.

METEOROLOGICAL RECORD.

Deaths reported 2,182; under five years of age 702; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 502, acute lung diseases 282, consumption 270, diphtheria and croup 60, diarrheal diseases 56, scarlet fever 50, influenza 3, erysipelas 12, typhoid fever 29, whooping cough 14, measles 12, cerebro-spinal meningitis 13, smallpox 10,

From whooping cough, New York 6, Pittsburg 5, Providence 1, Boston 2. From cerebro-spinal meningitis, New

York 5, Baltimore 2, Lynn 2, Boston, Worcester, Lowell and Cambridge 1 each. From scarlet fever, New York 38, Pittsburg 1, Boston 9, Worcester 1, Revere 1. From typhoid fever, New York 11, Baltimore 1, Pittsburg 12, Boston 3, Haverhill 1, Newburyport 1. From erysipelas, New York 4, Baltimore 3, Providence 1, Boston 3, Chicopee 1. From smallpox, New York 10.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending April 20th, the death rate was 18.4. Deaths reported, 4,159: acute diseases of the respiratory organs (London), 374, whooping cough 108, diphtheria 39, measles 117, fever 27, scarlet fever 20.

The death rate ranged from 10.8, in Burnley, to 25.4, in Wolverhampton; Birkenhead 19.2, Birmingham 21.6, Blackburn 19.5, Bolton 19.4, Bradford 16.1, Brighton 15.0, Bristol 18.4, Cardiff 12.3, Croydon 13.5, Derby 17.1, Gateshead 22.3, Halifax 11.2, Huddersfield 14.8, Hull 18.0, Leeds 20.3, Leicester 16.2, Liverpool 22.9, London 17.5, Manchester 22.7, Newcastle-on-Tyne 20.4, Norwich 16.6, Nottingham 23.7, Oldham 14.4, Plymouth 13.1, Portsmouth 19.1, Preston 18.2, Salford 18.7, Sheffield 21.9, Sunderland 22.0, Swansea 20.4, West Ham 11.9.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, WEEK ENDED MAY 11, 1901.

J. S. TAYLOR, assistant surgeon, detached from the Manila, and ordered to the Naval Hospital, Yokohama, Japan.

F. L. BENTON, assistant surgeon, detached from the Naval Hospital, Yokohama, and ordered to duty on the Asiatic Station.

E. Z. DERR, medical director, detached from the Naval Academy, and ordered home to wait orders.

F. W. F. WIEBER, surgeon, detached from the Naval Station, San Juan, and ordered to the Naval Academy.

C. H. T. LOWNDES, surgeon, detached from the Lancaster, May 11th, and ordered to the Naval Station, San Juan, P. R.

E. S. BOGERT, passed assistant surgeon, ordered to the Lancaster, May 11th.

L. W. Curtis, surgeon, detached from the Vermont, May 11th, and ordered home and to be in readiness for sea duty.

G. PICKRELL, surgeon, ordered to the Vermont, May 11th.

C. F. STOKES, surgeon, detached from the Asiatic Station, and ordered home via mail steamer.

SOCIETY NOTICES.

AMERICAN DERMATOLOGICAL ASSOCIATION.—The twenty-fifth annual meeting of the American Dermatological Association will be held in Chicago, May 30 and 31 and June 1, 1901.

MASSACHUSETTS MEDICAL SOCIETY.—The annual meeting of the Massachusetts Medical Society will be held at 9.30 A.M., Wednesday, June 12, 1901, in Chickering Hall, on Huntington Avenue, near Massachusetts Avenue, Boston. Meetings of Sections will be held in the Medical Library, 8 The Fenway, on the preceding day, Tuesday, June 11th.

RECENT DEATH.

IRVING C. ROSSE, M.D., of Washington, died in that city on May 3d, at the age of fifty-four years. He was graduated from the medical department of the University of Maryland in the class of 1866. He served in the medical corps of the United States Army during the Civil War and later. He was a member of the American Medical Association, of the Medical Society of the District of Columbia, of the American Anthropometric Society of the American Neurological Association, and of the New York Medico-Legal Society. He was a frequent contributor to medical literature, especially in the line of neurology and psychiatry.

BOOKS AND PAMPHLETS RECEIVED.

Circular No. 3. War Department. Surgeon General's Office. Reprint. 1901.

A Plan for the Study of Man. By Arthur MacDonald, Washington, D. C. Reprint. 1901.

Zur Behandlung des Pyothorax. Von Prof. Dr. Carl Beck, New York. Illustrated. Reprint. 1898.

Ueber Tendinitis und Tendovaginitis prolifera calcarea. Von Carl Beck, New York. Illustrated. Reprint.

Ueber die Bedeutung der Röntgenstrahlen bei der Spina bifida. Von Prof. Dr. Carl Beck in New York. Reprint. 1898.

Keen, M.D., LL.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, and Wm. G. Spiller, M.D., Professor of Diseases of the Nervous System in the Philadelphia Polyclinic, Associate in the Pepper Clinical Laboratory, University of Pennsylvania, Philadelphia. Reprint. Illustrated. 1900.

Original Article.

MUNICIPAL CARE OF THE CONSUMPTIVE POOR.[1]

BY S. A. KNOPF, M.D., NEW YORK.

My first duty is to thank your distinguished president and the members of the Suffolk District Medical Society for the great honor you have conferred upon me by the invitation to address you this evening. For a stranger to be invited to read a paper before a medical body is always an honor; for a New Yorker to be invited by an audience of medical men of the great city of Boston, which, I think, should not only be called the Athens of America but also the American Athens of Medical Science, is an unusually great honor, and I wish to express to you my deep appreciation of it.

Boston was the cradle of anesthesia, the greatest blessing which was bestowed on mankind during the past century. It was here that the three great immortals of modern medicine, Bowditch, Holmes and Bigelow, gave to the world their wisdom and the experience of a long life's work, worthy of an Athenian of old. On the very subject about which I am going to speak, you, the sons, friends and pupils of these great modern teachers, have given to the rest of the American physicians, sanatarians and statesmen an example in the modern way of caring for, treating and curing the consumptive poor and those of moderate means. Your Sharon Sanatorium was the first of its kind to demonstrate the truth of a most important maxim in modern phthisiotherapy, namely, that the hygienic and dietetic treatment of pulmonary tuberculosis can be carried out with satisfactory results everywhere where the extremes of temperature are not too pronounced, and where there is relatively pure air and the condition of the soil and general environments are sanitary; also, that special climatic advantages, while a valuable adjuvant in phthisiotherapeutics, are no longer considered essential to the successful treatment of consumption. You all know of the excellent work this institution has done under the able directorship of Dr. Vincent Y. Bowditch; you are familiar with its results; but you may not know as well as I what a valuable lesson this work of Boston physicians has been to the rest of us. You have done the pioneer work in this direction, and in one of your neighboring towns an ingenious physician, Dr. C. S. Millett, of Brockton, has given additional glory to New England physicians by having demonstrated at East Bridgewater that the much feared New England climate is not only well suited to the treatment of patients in the various stages of pulmonary tuberculosis, but that even the New England night air can be advantageously enlisted as a factor in phthisiotherapeutics.

To you again belongs the honor of having the first State sanatorium in this country for the treatment of indigent consumptives in the primary stages of the disease. But you are not content with your laurels, you want to do more. You desire also to have the first city sanatorium, the first municipal institution in this country for the exclusive treatment of the consumptive poor. You are anxious to take care of those who can not get into the State sanatorium, the Sharon Sanatorium or similar institutions, depending for their support on private philanthropy. In other words, you wish to show that there must, can and should be municipal care of the consumptive poor besides the work the State or private philanthropy can accomplish.

I do not wish to discourage you when I say that the work which you are about to undertake is the most difficult of all, and the magnitude of it may seem at first appalling to some of you. You have, however, the reputation of being able to accomplish difficult things, and the record of the past shows what you can do when your cause is just and good, and you have the support of those who can and are glad to help.

Since you have honored me by asking my assistance, permit me first to show those to whom you may appeal for help and support the justice of your cause.

I will not burden this paper with many statistics, for you all know that pulmonary tuberculosis is the most prevalent of all diseases. You know, furthermore, that it is most frequent among the poor and in the most densely crowded quarters of great cities.

To demonstrate the difference in the mortality from, and morbidity of, tuberculosis in the various quarters of a city, and among the different classes of the population, I will only quote from three cities, namely, Paris, Hamburg and New York.

In the French capital the mortality from tuberculosis in the poorest quarters is 65 per 10,000 inhabitants. In the quarters occupied by the working classes about 50 per 10,000, and in the quarters of the rich it is only 20 per 10,000 inhabitants.

In Hamburg, among the people who earn less than $500 per year the death rate from tuberculosis is 40 per 10,000, and among those earning more it is only 15 per 10,000 inhabitants.

For New York I have been enabled from the existing maps of the Health Department, to which, thanks to the courtesy of Doctor Tracy, I had free access, to compile the following interesting figures: In the very poorest quarters, such, for example, as in the First Ward, near the Battery, where the Assyrians live, the mortality from tuberculosis is not less than 72 per 10,000 inhabitants. Next high in the death rate from tuberculosis comes Ward 4, which includes Park Row, where it is 63 per 10,000 inhabitants. Then comes Ward 8, that portion situated between Spring and Canal Streets, Broadway and Warrick, with 58; Ward 5, West of Hudson, between Read and Canal Streets, with 54; then Ward 21, the slaughterhouse district, above 40th Street, east of Second Avenue, also with 54; Ward 20, between

[1] Address delivered by invitation before the Clinical Section of the Suffolk District Medical Society, April 17, 1901.

26th and 31st Streets, West of Ninth Avenue, 54; and in the same Ward, between 31st and 40th Streets, between Ninth and Sixth Avenues, only 37; Ward 15, the lower half, between West 4th and Houston, Sixth Avenue and Broadway, mainly populated by French and Italians, 52; Ward 14, portion A, 50. In Ward 18, the portion east of First Avenue, the death rate is 49; and in the same Ward, near Madison Square, it is only 13. In the lower half of the Seventh Ward, largely populated by Irish longshoremen and sailors of all nationalities living in typical sailors' boarding-houses, the mortality from tuberculosis is 44 per 10,000 inhabitants; while in the upper part of Monroe Street, densely populated by Russian Jews, the mortality is only 35 per 10,000 inhabitants. In Ward 9, in Houston Street, west of Sixth Avenue, it is 43. In Ward 19, between First and Third Avenues, 54th and 70th Streets, where the artisans live, the mortality is 36. Ward 11 and 17 have a mortality of 35. Ward 10, the northern portion has 33, while in the southern portion, south of Grand Street, also populated by Russian Jews, it is 29. Ward 12, the portion situated between Columbus Avenue and Riverside Park, between 94th and 102d Streets, has only 18. The real wealthy portion of New York City, situated in Ward 19, between Park and Sixth Avenues, 50th and 59th Streets, has a death rate of 16 per 10,000 inhabitants. The same ward, between 70th and 76th Streets, Third and Fifth Avenues, has 11. That portion of the 22d Ward situated between Amsterdam Avenue and Central Park West, 66th and 77th Streets, has only 5, and Governor's Island, where our military posts are, has the smallest death rate from tuberculosis, that is to say, 3 per 10,000 inhabitants.

From the latest general statistics I could obtain, I learned that consumption was responsible for 11% of your own city's mortality.

However terrible as this mortality must seem, consumption is no longer considered a hopeless and incurable disease. It has been demonstrated that the early recognized case of tuberculosis has from 60% to 80% of chances of cure.

Not only living, but even the dead demonstrate the absolute curability of tuberculosis of the lungs. I know that some of my esteemed confrères in this city do not approve of the expression "absolute cure," when speaking of pulmonary tuberculosis, but prefer the more conservative expression, "arrested cases." But every one of them, I am quite sure, will acknowledge that there are a great many typhoid fever cases which will get absolutely well. In an absolutely cured typhoid fever case we would find, could we examine the inner lining of the patient's intestines, cicatritial tissue in the region of Pyer's patches. In the absolutely cured lung which was once invaded by the tubercles, we will find cicatritial tissue or a calcarious mass perfectly innoxious. I endeavored to collect statistics from the pathological records from all over the world for my little work on tuberculosis.[2] From them I learned that almost 25% of the people who died of accidents or diseases other than tuberculosis, showed in post-mortem examination evidences of absolutely healed pulmonary lesions. If I add to this evidence from the dead my personal experience with many living, and very much alive, former consumptives, who were considered phthisical as many as thirty years ago, my colleagues will understand my enthusiasm and reasons for preferring the word "cured" to the expression "arrested cases."

Pardon this little diversion from the real subject, but we must, in our combat against tuberculosis be permeated with the one great idea that pulmonary tuberculosis is not only an eminently preventable but also a very curable disease.

Statistics show that the mortality from tuberculosis is most frequent between the ages of seventeen and thirty-five, just at a period when the individual should be a most useful member of society, a breadwinner and, if possible, a supporter of a family.

Your presence here tonight is a strong protest against existing conditions which still allow such fearful mortality. You know it is in the power of man to prevent this great loss of life, this great economic loss to the community and the calamity which is brought to many a family by the untimely death of some of its members. You ask why should this city lose thousands of persons every year from a disease which can be prevented and cured, and thus suffer a far greater material loss than had the community provided for timely treatment and care of the consumptive poor. It is this class of poor who, owing to the peculiarity of the disease, are more dependent upon municipal care than any other class of people. I know that you have here in Boston not quite such a bad tenement-house system as we have in New York, but those of you who labor among the poor will bear me out when I say that even a Boston tenement home is not a fit place for a consumptive to live in.

The most essential requirements for the treatment of a consumptive are good pure air, and plenty of it; sunshine, and plenty of it; good food, and plenty of it; medical supervision, and plenty of it. Six hundred cubic feet of space should be the minimum allowance for an adult person in the state of health; the consumptive should have rooms with at least a thousand cubic feet of air at his disposal, day and night. You know how little sunshine enters in some of the tenements of your own city.

The nutrition a poor consumptive receives depends largely upon what member of a family he may happen to be. If it is the son or daughter the patient will probably not be in want of food. The parents will gladly provide for the needs of their loved one; but if the consumptive sufferer is the father or mother, and particularly if the father is the invalid and unable to work, there will be economizing with the savings of better days, and the food furnished for the invalid must of necessity be scanty. If, finally, the wife has to take up

[2] Knopf: Pulmonary Tuberculosis; its Modern Prophylaxis and the Treatment in Special Institutions and at Home. Philadelphia: P. Blakiston's Son & Co.

the burden of supporting the family, there will be still greater distress, for the patient will not only lack the necessary food, but he will also be deprived during the day of the presence of his companion who made his sufferings bearable by the thousand little attentions which only a devoted wife knows how to bestow. I have had, in my work as a phthisiotherapeutist, opportunity to know the life of the tenement dwellers. When everything goes well, when the husband is industrious, sober and at work, the wife intelligent, and the children not too numerous in the family, they are, as a whole, a happy lot of people. But when sickness comes, and particularly when that chronic and communicable disease, consumption of the lungs, strikes one of the tenement dwellers, the family's happiness is doomed. Tuberculosis is a disease which is costly. The first thing the doctor, if he should be called in, will prescribe, is better food, meat, plenty of milk and eggs. He will probably also urge them to buy another bed, for the conscientious physician will insist that the consumptive patient has his own bed, preferably also his own room. And, nevertheless, even if these latter precautions are carried out, the close proximity in which tenement families live makes the communication of the disease to others almost inevitable. There is, to my mind, no sadder fate than to be a poor consumptive having a family depending upon him for support. Everything that is needed to prevent or cure consumption is lacking in the tenement of the poor, and even the most careful, conscientious and experienced physician knows that when he is in the presence of a consumptive man or woman of the poorer class, who are forced to continue to reside in their unhygienic homes and unsanitary environments in general, all his efforts to save this life will be of no avail. It is the old story; the prognosis of consumption depends, alas! only too often as much upon the money bag of the patient as upon all the other factors. The physician may be willing, and I know he always is, to give his service gratuitously, but he knows that without a better and richer diet, careful nursing and an improved hygiene, his devotion will be useless.

What are we to do for the thousands of cases of that kind in your own and other cities? I cannot advise to you anything new, but only emphasize what others have said and proposed, and add, perhaps, a few suggestions which are not feasible everywhere, but may be feasible in the good city of Boston.

I have learned that there is now a bill before your legislature for the establishment of a second State sanatorium, and before your city government there is a similar bill for a city hospital for consumptives. This is a right beginning, and there is not a shadow of doubt in my mind that both bills will pass unanimously and be approved by the distinguished chiefs of your State and city. If you desire to know what makes me so sanguine, so sure of all this, I will gladly tell you. When preparing this address, I had before me *Charities*, the official organ of the Charity Organization Society of the city of New York, and here is what I read in an editorial of that paper of March 23d: "In the city of Boston, the helpless and unfortunate poor have a larger number of friends from the classes of the well-to-do than in any other city with whose needs and resources we are familiar. The evidence of this is abundant. They abound upon the boards which are at the head of the various city departments having charge of children, destitute adults and delinquents. They enroll by the hundreds for volunteer friendly visiting. They show in countless ways, even when not thus professionally connected with charitable activities, that they have a personal interest in the alleviation of distress and in the prevention of future dependence. Their views prevail before legislative committees and police commissions, in the mayor's office, and at the seat of executive State government. It is the normal and usual thing for the men, and, to an even greater degree, for the women, of Boston, whether they have had training in the Associated Charities or not, to have some familiarity with the elementary principles of charities, and in that fortunate city many fundamental axioms may be taken for granted which elsewhere have not been learned, or have been forgotten."

Your State legislature and your distinguished governor, your city fathers and your honorable mayor, will not only give you these two institutions and as many more as may be needed, because they are charitably inclined, but they know that through such wise legislation they will not only protect their fellow-citizens from the danger of contracting tuberculous diseases, but they also know that through such provisions a large majority of consumptives will be cured and made again breadwinners and supporters of their families. Thus they are prevented from becoming a burden to the community, and there will be not only a great saving of lives, but also in the end a considerable saving of money to the treasuries of the State and municipality.

There are in all communities people whom it is hard to convince by indirect proofs. To them I desire to say that by treating a consumptive patient in a sanatorium or special hospital, where he has from 50% to 75% of chances of cure, instead of treating him in your general hospital, where his chances of cure, in spite of the best of care, must be considerably less, the Commonwealth saves on each patient $4.00 for every week when treated in a sanatorium.

According to the "Third Annual Report of the Trustees of the Massachusetts State Sanatorium for Consumptives," the weekly cost of maintenance per patient has been $8.40. According to the kind information furnished me recently by Dr. Geo. H. M. Rowe, Superintendent of the Boston City Hospital, the average cost per patient per week last year was $12.40.

To cure the curable patient in a sanatorium or special hospital requires from eight months to one year. The average length of stay of the incurable consumptive patient who enters the hospital,

from the day he is no longer able to work up to the date of his death, is about the same, that is to say, six months to one year. It requires no great arithmetical calculation to show the immense financial benefit which must accrue to the Commonwealth by taking care of the consumptive while still in the incipient stage.

From the same letter, which Dr. Rowe had the goodness to send me, I learned that, as a rule, patients with pulmonary tuberculosis are not admitted to the Boston City Hospital; but, as a matter of fact, in the course of a year they take in a considerable number. Cases of chronic phthisis where there is a hemorrhage or urgent symptoms, or people found in great distress, are brought there for temporary treatment. The charity characteristic of you Boston people allows here an infringement upon the rules of your hospital for humanity's sake; for, in reality, a general hospital is no place for consumptives, no matter in what stage of the disease. What is needed for the treatment of such people, such as large spacious rooms, rest-cure galleries for the open-air treatment, special hydrotherapeutic arrangements for the application of cold water, constant medical supervision, and so on, is not easy to be had in a general hospital.

While I have no doubt that in your excellent City Hospital the greatest care is exercised to avoid possible infection from the consumptive's sputum, so that he may not endanger his fellow patient suffering from typhoid fever, rheumatism or pneumonia, or enfeebled by surgical operations, there still exists the drop infection. Small particles of bacilliferous saliva may be expelled by the patient passing through the ward, during the so-called dry cough, sneezing, or loud and excited talking. In short, it requires more special care to prevent a consumptive from doing harm to his fellow patients and to himself than can be bestowed upon him in a general hospital. At night, when the consumptive patient in the ward of a general hospital would like to have his window open, the rheumatic neighbor might object, and in revenge the untrained consumptive might keep the whole ward awake with his cough.

To those of my hearers who are not familiar with the treatment of consumptive patients in a sanatorium or special hospital, I wish to add here for explanation that the consumptive in such institutions is only allowed to cough when he has to expectorate, at all other times he is taught that coughing without expectoration is not only useless and harmful, but also impolite. But, besides this discipline of the cough, the patient in the sanatorium learns a great many other things. He is taught that he must be religiously clean and careful with his expectoration and other secretions, and that any willful violation of the rules and regulations concerning the sputum means immediate dismissal from the institution.

Patients in the sanatorium are trained how not to take cold, what to do in the case of this or that accident which may befall them during the course of the disease, what to avoid and what to do in order to continue on the road to recovery. The regular life which the consumptive leads and the hygienic training which he receives in the sanatorium are of inestimable value to himself, to his family and to the community. If completely or if only partially cured from his disease, this former inmate of a sanatorium will constitute a hygienic factor among his neighbors and friends on his return home.

There is one more benefit derived by the community, and also individuals, from the sojourn of consumptives in sanatoria, which has thus far not been highly enough estimated in this country, but which has been frequently observed and appreciated in Europe. The consumptive persons addicted to the abuse of alcoholic beverages have to lead, when they become inmates of a sanatorium for tuberculous patients, such regular and sober lives that with the improvement of their functions of nutrition and assimilation, one of the essential factors of the sanatorium treatment, they will very often reform, and on their discharge from the sanatorium will not only have regained their health and vigor, but also have become morally better men and women by having lost their desire for strong drink.

The physician in the sanatorium for consumptives is the close friend, advisor and educator of all his patients, and the modern sanatorium for the treatment of consumptives (poor and rich) must be, and is, a school of hygiene.

Let those who still doubt the need of more institutions in your city and State, or who claim that the American patient does not like sanatorium life with its discipline, as do patients in European sanatoria, read the latest report of Dr. Marclay, superintendent of the Rutland Sanatorium, wherein he says: "There have appeared, from September, 1899, to September, 1900, for entrance examination, 1,233 applicants, of whom 69% have been rejected because there were no prospects of immediate vacancies or because of too advanced condition of the disease."

It is not impossible that in your city or in your State there will be, and I have found them nearly everywhere, people who object to the establishment of a sanatorium or hospital for consumptives because they live near or have property in the vicinity of the future institution. To those who fear contagion from a sanatorium I will simply say that if they desire, I will be able to furnish them with official statistics for over fifty years, whereby it is conclusively proven that, since the establishment of sanatoria for consumptives, the mortality from tuberculosis among the villagers of Gœrbersdorf and Falkenstein, the two places where five of the most flourishing German sanatoria are now existing, has actually been decreased to one-third of that which it was before the establishment of the institutions. The explanation for this remarkable decrease of consumption in the villages of Gœrbersdorf and Falkenstein is simply to be sought in the fact that the villagers imitated voluntarily the clean habits which were obligatory for the sanatorium inmates.

To those who fear a depreciation of their property because poor consumptives will come near it, I will relate the following anecdote which happened a few years ago: Near Vienna existed a place which had been known for years as a health resort for consumptives and persons suffering from similar troubles. Thanks to the efforts of a distinguished professor and specialist in phthisiotherapeutics, and the funds given by wealthy philanthropists, it had been decided to found a sanatorium for poor consumptives, under the direction of this professor, in the resort mentioned. But the authorities of the community raised such an outcry at the prospect of having this institution in their midst, fearing it would drive away the class of wealthy patients who had come there for so long, that the professor, not wishing to go where his sanatorium would not be welcome, chose another locality. They thought they had done a wise thing; but soon the wealthy patients, thinking that the new place must possess superior advantages to have been chosen for his institution by so celebrated a specialist, began to flock thither, and the old resort, so favored for years, found itself quite deserted.

Besides the one or two city hospitals which you are going to have, and the second State sanatorium, you should have an especially constructed building which should serve as a large dispensary and reception hospital for tuberculous patients, from whence the cases for the city hospital or State sanatoria should be selected. Furthermore, I must plead with your city and State authorities to create, at not too great a distance from your city, and near the seashore, a sanatorium for the treatment of scrofulous and tuberculous children. If one considers the very large percentage of scrofulous and tuberculous children among the poor, it is simply surprising that the many wealthy communities along the seashores of this great country have not long since established sanatoria for these unfortunate little ones. It is a well-known fact that a seacoast climate, in connection with good food and treatment, acts almost as a specific in the treatment of scrofulous and tuberculous afflictions in childhood.

In France, Holland, Germany, Italy and the Scandinavian countries, there have existed for years a large number of seaside sanatoria for the exclusive treatment of tuberculous and scrofulous children. The results obtained in these institutions, which include surgical tuberculosis as well, vary from 60% to 75% of complete recoveries. To many excellent schools are attached, so that the children's general education is not neglected. That such children's sanatoria are most essential factors in the solution of the tuberculosis problem is evident, when we consider that they have both the mission of prevention as well as of cure.

Lastly, I desire to ask of the managers of your maternity hospitals to set apart the best-lighted and best-ventilated wards and rooms for the exclusive treatment of tuberculous pregnant women. To begin the hygienic and dietetic treatment, as far as it is practicable, in such an institution and as long as possible before the confinement, and to see that it is continued afterwards at least for a year in a sanatorium or at the home of the mother, will save many a life.

Having now all our institutions, let us see what plan may be formulated in order to cope intelligently, practically, and with the hope of the greatest possible success, with the tuberculosis problem in your city and State. The first thing to be done would be to form a tuberculosis commission. This commission should be composed of physicians in the employ of the city, of sanitary officers, officers of the charity organizations, and of friends of the poor from the well-to-do of your good city, of which my friend, Dr. Edward T. Devine, editor of *Charities*, has spoken so eloquently. This commission would have its headquarters in the city dispensary for tuberculous patients. Its work would consist: Firstly, in determining the applicant's condition by a medical examination. If his condition demands it, he should be immediately placed in the reception hospital or assigned to one of the dispensary classes for treatment. Secondly, in the meantime the members of the tuberculosis commission on duty should visit the home of the patient and institute such hygienic measures as seem necessary to prevent further contamination. Thirdly, the medical member of that commission should examine the other members of the family in order to find out if any of them have also contracted the disease, and if so, counsel proper treatment. Fourthly, the commission will then make a full report to the sanitary authorities as to the condition of the patient's dwelling. Its thorough disinfection, renovation, or even destruction may become imperative when it is evident that tuberculosis has become endemic there owing to the continued residence of tuberculous invalids, the condition of the soil or other sanitary defects. Fifthly, the commission, the laymen of which will, of course, be drilled, so to speak, in the prophylaxis of tuberculosis, will have become real sanitarians, must help the doctor by distributing literature and by verbal advice to teach the families they visit the essentials of prevention of tuberculosis and hygiene in general. Lastly, the commission, being in touch with all the charity organizations of the city, will determine the financial condition of the applicant to the dispensary, special hospital or sanatorium; for we must not encourage abuse of medical or any other charity. If he is able to pay he should be made to pay; if he is poor, by all means extend to him the full benefit of charity. Nay, even if, by his being taken to an institution, the family should become destitute, it would be the imperative duty of the commission to see that the remainder of the family be protected from want by either public or private philanthropy. A letter of inquiry sent to the former physician of such a patient, if he has had one, might often aid the work of the investigating commission. Of course, it goes without saying that every member of the medical profession will be helpful in this work

by referring needy tuberculous patients to the investigation committee.

This, Mr. President, members and friends of the Suffolk District Medical Society, is all I have to suggest, and it only remains for me to wish you all God-speed in the work of combating one of the greatest scourges of the age, which was so justly called by your own Oliver Wendell Holmes, "the great white plague." You have done, already, more than any other State in the Union; there are prospects that, ere long, you will have done more than any other city in the Union, and I feel confident that it will be within your own borders that tuberculosis as a disease of the masses will first disappear.

Clinical Department.

ECHINOCOCCUS OF LIVER WITH PERFORATION INTO THE LUNGS AND BRONCHI.

BY WILLIAM F. GAY, M.D., BOSTON.

THE comparative infrequency of cases of this nature occurring in this country seems to be of sufficient importance to cause me to report the case briefly, although I have nothing new, perhaps, to offer, except what may be found embodied in the current literature of the subject by the various authors on medical practice, and bearing out the idea that symptoms of this disease are rarely prominent and may be so marked by intercurrent diseases, as in my case, that an absolute diagnosis is not possible until a rupture occurs, and the characteristic cysts and hooklets are demonstrated.

On January 10, 1901, I was called to see Angelo T., male, Italian, four years in America, age twenty-five, barber. On account of his inability to speak much English, I could only elicit the following as to his past history: Always ailing, more or less, up to fourteenth year, with cough, fever and general weakness. Then fairly well until his twenty-third year, about October or November, 1898, when he was operated upon in Boston City Hospital for (dropsy?). The scar showing a median laparotomy. History of slight attacks of hemoptysis, and more or less pain constantly in dorsal region. About December 1, 1900, he became quite ill, much cough, with blood streaked expectoration, headache and anorexia and marked debility, chills and moderate fever, with pain in the lower right side of chest.

On date of my first visit I found the patient much prostrated; emaciation moderate, face showing a dusky pallor, tongue heavily coated, temperature 100.8° F., pulse 98, and respirations 30 per minute; bowels constipated. The physical signs showed diminished respiration, crepitant and subcrepitant râles, slight dulness at base of right lung, small mucous râles and crackling at both apices with sinking in of the supra clavicular spaces, with dulness slight over both apices and jerky respiration. The dulness at base of right lung increased, bronchial breathing, rusty sputum and rising temperature, with other symptoms, pointed to a right lower lobar pneumonia, with coexistent phthisis pulmonalis.

The pneumonia followed the usual course, and at the end of January the patient had recovered from it and was up and about, the lower right lung having cleared up, the other portions remaining about the same. At this time my attention was attracted to the liver, which was slightly painful and gradually enlarging.

During February the patient continued to gain strength, the appetite increased, and, save for a peculiar pallor and the liver enlargement, there were no noteworthy symptoms.

March 1st, I was called to see patient on account of several attacks of hemoptysis the previous day, and found him with much cough and bloody expectoration. Under treatment the hemorrhages ceased in a few days and the expectoration became viscid and white. The lungs showed a general acute catarrhal condition with a multiplicity of râles of all kinds. The liver at this time, however, showed considerable uniform enlargement, very firm and smooth and appreciable to the eye. The right lobe extended on a line about two and one-half inches above the umbilicus, the left lobe well into the left hypochondriac region; considerable abdominal tympanites, raised surface temperature, much pain on coughing, bowels inclined to constipation and feces clay-colored, fetid and pasty. There was, however, no jaundice, other than a peculiar pallor which could be called dusky, anxious expression, pinched features and cold sweats. Temperature 101°, pulse 120, respiration 32, with occasional attacks of stupor.

This train of symptoms continued for about a week, the breathing became labored, the liver more painful, and on March 13th had reached the maximum. Temperature was then 101.2°, pulse 134, and respiration 40. On March 14th the patient had several vomiting spells, the matter ejected being of a bright yellow color, suggesting bile. The expectoration became more copious and of bright orange color, and in a few days the temperature declined to about 99°, the breathing became less labored, the liver softer and decreasing in size, and the general condition, from being alarming, slowly improved.

The diagnosis of a perforation from the liver into the lungs and bronchial tubes was made, although I was at a loss to understand the exact condition of the liver giving rise to it, as the substance raised was not fetid nor pus-like, and the bright orange color was something I had never seen nor read about. Finding a small fragment of a whitish hyaline membrane in the sputum caused me to suspect hydatids, and, upon close search of the sputum every day, I was soon rewarded by finding an entire cyst about the size of a pigeon's egg. The expectoration of the cysts then became more common, and from one to ten per day of various sizes ranging from a pea to a pigeon's egg. A diagnosis of echinococcus was made, and upon submitting several of the cysts to

F. B. Mallory, M.D., pathologist at the Boston City Hospital, was kindly confirmed by him, he finding the characteristic lamellated cyst structure, daughter cysts and scolices, the orange color being due to crystals of hematoidin.

April 10th. The patient at the present time is holding his own, the expectoration is decreasing in amount, the orange color is disappearing, the temperature remains about 99°, having touched normal once or twice, although the pulse rate still remains at from 110 to 120, seemingly uninfluenced by the undulations in temperature. This strain on the heart, together with the general phthisical consolidation of the lungs, will probably prove the fatal factors in the case.

The main points of interest in the case, as I have tried to show, is the fact that intercurrent disease fully met all the prominent symptoms, and prevented a positive diagnosis until rupture occurred and the cysts were microscopically demonstrated, the temperature never reaching above 101° F., except during the pneumonia, when it reached 102°, the high pulse rate, uninfluenced by the temperature, the peculiar orange-colored masses in the sputum, the absence of pleuritic involvement at the time of perforation, and the presence of the cysts.

MASSACHUSETTS GENERAL HOSPITAL. CLINICAL MEETING OF THE MEDICAL BOARD.

(Concluded from No. 20, p. 476.)

DR. J. P. CLARK gave an exhibition of a

CASE OPERATED ON FOR EXAGGERATED ROMAN NOSE.

The patient whom I have to present shows the result of a cosmetic operation on an exaggerated Roman nose. The photographs and plaster casts, which I pass around, show the appearance of the nose before and after operation. The credit of devising this method of operating in such cases belongs to Dr. Goodale, and he has reported 1 case.[2] The operation, as I performed it on my patient, was as follows: A pair of short curved scissors was introduced into the left nostril. One blade was made to perforate the septum just beneath the lower end of the prominence which I wished to remove. Then, with the convexity of the scissors uppermost, the septum was freed from the prominent portion of the nose, following as closely as possible the outline of the prominence. The extremities of this curved cut were then connected by a straight cut with a pair of straight scissors and the loose piece of septum removed with forceps. Next, a small nasal saw was introduced into one nostril and the nasal bone was sawed through as nearly as possible at its junction with the nasal process of the superior maxilla, care being taken not to injure the skin. The same thing was done to the other nasal bone. Now, using the padded handle of a tongue-depressor as a pleximeter to prevent bruising the skin, a few gentle taps with a small mallet on

the nasal bones sufficed to break the frontal articulation and depress them, still firmly united with each other, until they came into contact with the upper margin of the septum, the sawed edges of

the nasal bones sliding down inside the nasal processes of the superior maxilla. The right nasal

[2] See Boston Medical and Surgical Journal [of February 2, 1899.

process of the superior maxilla was now seen to be too prominent. A gentle blow on this, using the same plexímeter, easily fractured it, and an even, symmetrical surface was obtained. The nose was held in the desired position by means of suitable pads and a bandage for two weeks. By this time the bones were sufficiently firmly united to dispense with any splint. The interior of the nose now shows no evidence of any operation, in fact, the nasal cavities appear perfectly normal.

DR. C. B. PORTER reported several cases of plastic operation.

PLASTIC OF HAND.

B. McL., age twenty-three, single, burned her left hand in a mangle July 30th, was treated in the Out-Patient Department for three weeks, thence referred to House for Grafting on August 20th.

Operation August 22d, by Dr. Balch, when the palm was attached to a flap reflected from the abdomen. This flap covered the palm and overlapped the first phalanges of four fingers. The flap was freed from the abdomen September 4th, twenty-three days after.

Discharged September 18th.

Re-entry December 13, 1900, for superfluous fat in skin-flap, operation December 18th, when the fat was dissected from beneath the skin.

Discharged December 24th.

Re-entry January 8, 1901, for cicatricial contraction of the fingers. Operation, January 10th. Here the web between the fingers was removed by a plastic operation.

Discharged January 28th to seats.

PLASTIC OF ARM.

W. T. D., age five years, on June 6th received severe burn of anterior surface of left arm and forearm to shoulder. Treated in Out-Patient Department for two weeks and admitted to house June 23d for skin grafting. This was done July 2d and August 7th.

Discharged September 7th. Treated in seats for granulations of arm.

Re-entered November 17, 1900, for cicatricial contraction of elbow. Only 10° of motion, that is, flexion to a right angle. Extension 10° above right angle.

Operation December 15th, plastic of skin from abdomen to arm, etc. Operation January 4th, separation of flap from abdomen.

ENTEROPTOSIS.

J. Q., age forty-two years, married.

Entry January 1, 1901. Married twenty-two years, seven children. Lump in right abdomen seven or eight years ago, lasted one year. Tumor reappeared later and grew steadily for four years as a hard lump in the right side. At the end of this time was pregnant and delivered a nine months child. Three hours after birth of child this mass was delivered, the size of a baby's head. Shortly after, the tumor reappeared for the third time, and has been there ever since.

Operation on January 12th for radical cure of enteroptosis.

Discharged February 4th for treatment of heart disease.

DR. ELLIOT: Apropos of the young lady who had the accident with the mangle, two or three years ago I had very much the same sort of person as this who had her hand caught in a mangle. One roller in the mangle is hot and the other cold. The back roller is the hot one, and it took everything off the back of the hand down to the bone. I waited to see what could be done about it, and finally it cicatrized and, to my surprise, that is a a perfectly useful hand; though the extensor tendons were gone, the cicatricial tissue took the place admirably.

DR. J. M. JACKSON showed

A CASE OF MYXEDEMA AND ARRESTED DEVELOPMENT.

The patient, although nineteen years old, has the appearance of a girl of eleven. She is 50 inches tall and weighs 72 pounds, and one's first impression on looking at her is that she is a cretin, but on talking with her it is soon evident that she is a bright girl, though a little slow.

Her history is briefly as follows: A negative family history, except a possible specific disease in mother years ago. She had measles, chicken pox and whooping cough as a child. Began school at five years and graduated at fifteen years from grammar school without ever missing a day. Was a good scholar and stood well at school. Has since learned stenography and typewriting, though she is not very proficient as yet. She grew and developed like other children up to the age of eleven, since which time there has been no further growth. The mother says that the child used to have a high forehead, but that her hair has gradually encroached upon it, until, as you see now, the forehead is low and wrinkled. The teeth came in regular order except the eye teeth, which are just now erupting. The catamenia appeared last December for the first time.

Physical examination. — Undeveloped, but well nourished, muscles well developed. Height, 4 feet, 2 inches; weight, 72 pounds. Skin and mucous membranes of good color. Hair coarse and dry and comes low down on forehead; forehead wrinkled. Expression intelligent, speech rather slow, intellect clear. Skin dry, scaling and harsh. Thyroid not felt. No pads over the clavicles. Pupils equal and react normally. Epiphyses not enlarged. Bones small but normal. Tongue large, moist and clean. Teeth good, throat negative. No glandular enlargement, no pubic or axillary hair. Chest broad and short, no rosary. Breasts only slightly developed. Lungs normal. Heart, area of dulness normal, sounds regular and of good quality, no murmurs. Pulse slow, regular rhythm, good volume and tension. Abdomen full and rounded, not distended, no tenderness. Liver and spleen not enlarged. Legs long in proportion to the body, but otherwise normal. Knee jerks present or equal. Plantars normal. Marked

flatfoot of both feet. Temperature varied from 97° to 98°. Blood, hemoglobin 62%; whites, 8800. Urine, slightly pale, slightly acid 1020; chlorides normal; albumin, slightest possible trace; sugar absent; sediment slight, a rare squamous cell and leucocyte.

Treatment.—It is too late to expect much from treatment, but on account of the coarseness of hair, dryness of skin, and the greatly retarded development, I have put her on thyroids.

Dr. Fitz remarked that the case shown by Dr. Jackson is suggestive of the possible occurrence of a myxedema of adolescence in contrast to the congenital infantile and adult varieties.

The coarse, dry hair of the head, the absent axillary and pubic hair, and the conformation of the skeleton are what might be expected in a case of infantile myxedema. The low forehead and peculiar profile resemble those of sporadic cretinism, while the juvenile mental development corresponds with that observed in certain cases of infantile myxedema after treatment with thyroid extract.

Anatanical evidence of the condition of the thyroid in similar cases is lacking, but it seems not unreasonable to suppose that atrophy of this structure may be found as the cause of the arrest of development.

Medical Progress.

REPORT ON PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., AND H. W. CUSHING, M.D., BOSTON.

(Concluded from No. 20, p. 478.)

MESENTERIC CYSTS.

Dowd [19] presents a very interesting paper which he read in part before the New York Surgical Society, December 27, 1899. The following summary is given:

(1) The occurrence in the transverse mesocolon of a multilocular cystadenoma which contained pseudomucin, and which was exactly like the cystadenoma of the ovary, suggests its probable origin as an embryonic ovarian sequestration.

(2) The occurrence of dermoid cysts in a similar position suggests a similar origin.

(3) The occurrence of chylous cysts in the mesentery, which have the structure and appearance of ovarian and parovarian cysts, and which have in their walls lymph vessels, suggest embryonic cysts into which there has been an effusion of chyle.

(4) The sanguineous cysts appear to be preformed cysts into which hemorrhage has taken place; hematomata in the mesentery should not be described as cysts.

(5) The presence of cysts which have the structure of the intestinal wall suggest sequestration from the intestine.

(6) Serous cysts are apparently similar in origin and structure to the cysts already considered. They are usually not situated in the path of the lacteal vessels.

(7) Hydatid cysts form a class by themselves, and are due to the Tænia echinococcus.

(8) Reports indicate that mesenteric cysts are being removed at least as often as once a month. If microscopical examinations of the cyst walls and chemical and microscopical examinations of the cyst fluid are made, the entire subject should soon be understood.

(9) It is probable that all mesenteric cysts may be included in the classifications, (*a*) embryonic cysts; (*b*) hydatid cysts; (*c*) cystic malignant disease.

[19] Annals of Surgery, October, 1900, p. 515.

SUTURE OF ARTERIES.

Dr. Julius Doerfler [20] (Rostock) reports 2 successful cases of suture of arteries performed by Barre. In the first instance, a continuous silk suture, embracing adventitia and media, was applied laterally to the internal carotid injured in the course of the extirpation of carcinomatous glands. Result: Primary union; but at the post mortem, three months later, inspection of this vessel was overlooked (?).

On a second occasion, for a traumatic aneurism of the brachial, four interrupted silk sutures penetrating the intima were applied to the wound of the brachial, embracing half of the anterior circumference of this vessel. Result: Primary union; pulsation in the radial and ulnar weaker than the opposite side, and a distinct pulsation was visible below the site of suture.

These 2 cases bring the number of successful artery sutures recorded in literature up to 9. No failures have at least been published.

Experimentally, the author has determined that an aseptic thread jutting into the lumen does not cause any interference with the patency of the vessel; therefore he sees no danger in having the suture penetrate all the coats of the vessel. Any oozing from the needle punctures not controllable by pressure can be mastered by suture of the vessel sheath, or by covering it with an adjoining

[20] Annals of Surgery, November, 1900.

slip of muscle or fascia. Wounds of greater extent than half the circumference call for the Murphy invagination method.

Indications for suture are: Accidental wounds, stab, gunshot, or lacerated wounds; injuries inflicted during operation; traumatic aneurisms. Rigid asepsis is a requisite for successful suture; therefore an infected wound offers no field for this procedure. Whereas the skin incision should be free to gain access to the vessel, the sheath should be spared as much as possible, and the vessel itself subjected to as little stretching as possible. To render the vessel free from blood, proximal and distal pressure digitally is to be preferred; this failing, strips of gauze or forceps covered with rubber have to be used. Cambric needles armed with silk proved most useful for suture. Twelve experiments on animals performed with these precautions proved successful.

The Murphy method of invagination is indicated when more than half of the circumference is implicated, or when the laceration is extensive, or when traumatic aneurisms are not amenable to ordinary suture, or when a vessel has to be resected in the course of removal of new growths.

The author is wholly in favor of the invagination method as based on the successful outcome of his animal experiments and the three successful results in man. A particularly grateful field is augured for this method in aneurisms.[21]

THE TREATMENT AND PREVENTION OF CONTRACTION OF THE KNEE JOINT.

Carl Bruns[22] has relieved 3 cases where contraction of the knee following injury or inflammation caused great functional disability and pain by transplanting the flexor tendons of the thigh (biceps and semitendinosus) with the quadriceps femoris. He considers that it is not the capsule, fascia or skin that causes the contraction, but the muscles. The first patient was a child, eight years old, where the contraction followed septic arthrosis during infancy, and where a resection of the joint had been unsuccessful. The result at the end of five months showed a straight leg, and the patient could walk without pain. Before operation, when the stiff bandages were removed, the knee after a few days became flexed to 60°. In the other case the joint condition was the result of a nine-months' attack of gonorrheal arthrosis which resulted in the marked tendency to contraction and pain in walking. Unrelieved by bandages, apparatus, extension with anesthesia, etc. Relieved after a few weeks by the above-described treatment. The third case was the result of chronic articular rheumatism of several years' standing with 50° contraction. Patient bedridden. The writer claims that the method is one which can be satisfactorily substituted for resections in many cases.

TREATMENT OF INJURIES TO THE KNEE WITH HEMARTHROSIS.

C. Lauenstein,[23] after reviewing the various forms of treatment now in vogue for these cases — (1) "Expectant" treatment with massage and passive motion; (2) "ambulante" treatment; (3) rest, leg raised and ice; (4) immediate puncture of the joint and removal of clots by irrigation followed by fixation — concludes that the patients recover quickest when the joint is freed from blood clots and kept at rest for several weeks in a stiff bandage. That when the tear in the joint capsule is probably healed the patient is allowed to get up and begin motion of the joint. In cases of fractured patella he would evacuate the joint before applying the other dressings. He claims that this is the most rapid way of getting rid of the blood clots and placing the rent in the capsule in a favorable position for its union.

STATISTICS OF ONE HUNDRED CASES OF CANCER OF THE BREAST AND THE RESULTS OF OPERATION.

McWilliams, of New York, has given the statistics of 100 cases of cancer of the breast in a paper which appeared in the *Medical News*, April 28, 1900, p. 644, and he gives the following summary: Trauma present in 44.6% of the cases; married, 74% of the cases; children born to 66.6% of the cases; average number of children to each, 5; pain present in 56.2% of the cases; nipple retracted in 45.2% of the cases; right breast involved in 51 cases; left breast involved in 49 cases; axillary glands palpable in 48.9% of the cases; axillary glands found cancerous by microscope, 78.6% of cases; average age was forty-nine years, six months, twenty-six days; mortality of operation was 4%; average length of time in hospital, twenty days; prolongation of life for one year, 59%; prolongation of life for two years, 36%. Cured (no recurrence at end of three years), 34%; recurrence took place in one year in 21 cases; recurrence took place in two years in 28 cases; recurrence took place locally in 15 cases; recurrence took place in lung in 6 cases; average length of time in recurrent cases from operation to death, one year, two months, twenty days; average length of time from period of recurrence to death, five months.

THE VALUE OF PEDICLED FLAPS IN INJURIES OF THE HAND.

Dr. W. E. Schroeder[24] gives the following:

The injuries met with in the hand which result in the destruction of the skin and subcutaneous tissues, leaving the tendons and all or some of the bones and joints intact, may in many instances be repaired by judicious treatment. These injuries are commonly produced by various kinds of machinery and by burns and frostbites.

Amputation is freely resorted to in contused lacerated wounds of the hand, whereas burns are usually allowed to get well of their own accord; that is, plastic operations are not often performed. It is for such cases that the pedicled flap method is to be recommended.

Elasticity and resistance are required of the skin in the palm of the hand, and neither one of these conditions is furnished by the Thiersch or

[24] American Journal of the Medical Sciences, July, 1900.

free-flap method, although both of these methods may be used successfully on the dorsal surface of the hand. Enderlen, in his article, has shown that in Thiersch's graft the elastic fibres all die, and that only a very thin layer of epithelial cells remains. It is also insufficient because of the ulcers that form when the hand is used. He also cites cases where free flaps were used and the microscopical examinations of specimens showed that parts of them died, resulting in the formation of connective tissue. The author, with Dr. Fenger's permission, reports a case of this kind. He placed a free flap over the metacarpal bones from which the fingers had been removed, and found that in time the flap shrank decidedly, and when the stump was used small blisters formed, resulting in ulcers. Microscopical examination showed a considerable increase in quantity of connective tissue. It finally became necessary to replace this with a pedicled flap, which terminated favorably.

Where one desires simply to cover the palm, dorsum of hand, or the palmar surface of the thumb, flaps may be taken with freedom from the chest or abdomen. Where the palmar surface of the fingers has been destroyed, it is much better to have double pedicles, and these can best be obtained from the hip. Furthermore, this position is reasonably comfortable. I would say, however, that in young and old patients such a procedure would be very trying and scarcely justifiable.

Summary.— Advantages of this method: (1) Mobility; (2) elasticity; (3) certainty of taking.

THE CARDINAL PATHOGNOMONIC SIGN OF FRACTURE OF THE LOWER END OF THE RADIUS (COLLES).

Ware [25] calls attention to an old sign of Colles's fracture, which he considers the cardinal pathognomonic one. It is the sign of Langier, which he has found reliable in diagnosing 300 cases of fracture of the lower end of the radius that have come under his observation.

This sign is based on the relation of the ulnar and the radial styloid. The styloid of the radius is at a lower level than the styloid of the ulna. This is always the case, normally differing in degree according to the development of the bones, being more marked in males than in females, less so in infancy. With the hand in the prone position and on the same plane with the bones of the forearm, this sign is most readily ascertained by then impinging the thumb and index finger against the styloids, and projecting a line between the two points, it will take an oblique course slanting to the radial side.

An estimate of the existence of the levelling or elevation of the radial styloid should be the first maneuver in ascertaining a fracture, thus precluding any further manipulation until reduction is performed. It would suggest itself that this relation of the styloids ought to be an index to proper reduction; this is but relatively so, as an absolute restoration of the normal relation of the styloid is impossible in the greater number of instances. The presence of an altered relation in an old case indicates an old fracture.

TREATMENT OF OBLIQUE FRACTURES OF THE LEG.

N. Kæfer, Odessa, has treated oblique fractures of the tibia with marked shortening and marked tendency of the fragments to displacement by accurately applied plaster-of-Paris bandages and an especially devised apparatus for producing extension. The apparatus consists of a round iron rod of the thickness of a lead pencil, one end of which is cut with a right, the other with a left hand screw thread. Its centre has a nut-like projection. The rest of the apparatus consists of two pieces of metal, 10 cm. long and 1.8 cm. wide. One end of each is thickened and is bored so as to leave a hole 2 cm. long, into which the end of the first described rod can be screwed. The remaining surface is left rough. Kæfer's method consists of applying a bandage of plaster-of-Paris to the leg from the toes to above the knee. It should fit accurately, especially below the tibial tuberosities and above the malleoli. When nearly hard it is cut through transversely round the leg at the point of fracture. The parts of the apparatus bearing the female screw are placed on the edges of this cut, one on the upper half, one on the lower, and fastened in place by a few circular turns of stiff bandages. The rod is then fitted into the holes at the ends. When the bandage is hard by turning the rod, the cleft of the bandage is gradually widened and the leg extended. This extension is made gradually a little daily till the shortening is overcome. The apparatus is usually placed on the anterior surface of the leg. In one case reported, the upper half of the bandage was separated from the lower by the screw apparatus, a distance of 5 cm. in a few days. In the original article [26] a detailed description and illustration shows accurately the above-described appliance. The writer claims that his clinical experience shows that his apparatus has been a very efficient aid in the treatment of this difficult class of fractures and also in osteotomies.

STERILIZATION OF SPONGES.

C. A. Elsberg [27] claims to have found a method by which "reef" sponges can be sterilized by boiling without the deleterious effects which such a process usually produces with such substances. It is the following:

(1) Soak the sponges for twenty-four hours in an 8% solution of hydrochloric acid to remove calcareous substances and coarse dirt; (2) wash thoroughly in water; (3) boil five to twenty minutes in a solution of caustic potash 10.00, tannic acid 20.00, water 1000.00 —; (4) wash in sterile water or carbolic or sublimate solution until the dark brown potash-tannic acid solution is entirely removed; (5) keep in 5% carbolic solution.

This method, it is claimed, leaves the sponge with its original porosity, softness and elasticity

[26] Centrbl. f. Chir., 1901, Bd. xxviii, S. 1.
[27] Centrbl. f. Chir., 1900, Bd. xxvii, S. 7289.

even after repeating boiling of periods of one hour duration. Also that the same solution of caustic potash and tannic acid can be repeatedly used if the amount of evaporated water is replaced.

Sponges infected with staphylococcus aureus, streptococcus pyogenes and anthrax bacillus have always been found sterile after this method. Elsberg calls it a certain and simple method.

ON SURGICAL DISINFECTION.

Ochsner[28] describes the methods of surgical disinfection employed at the Augustana Hospital, Chicago. The following conclusions give a summary of his views:

(1) *a.* Theoretically it is almost impossible absolutely to disinfect the skin of the patient and the hands of the operator; *b.* practically it is one of the easiest and simplest tasks to obtain a degree of surgical cleanness that will insure primary wound-healing.

(2) *a.* Theoretically strong chemical disinfectants are indicated for the purpose of disinfecting the hands; *b.* practically careful washing with the mildest, namely, soap and water and alcohol, is absolutely sufficient and very much safer for the patient, because hands roughened by the use of the strong antiseptics are much more likely to become hopelessly septic than hands which are covered with smooth, healthy skin.

(3) *a.* Theoretically it is extremely simple to keep the hands aseptic after they have been rendered so; *b.* practically there is no more difficult task in any clinic than to keep all interested hands clean after they have been disinfected.

(4) *a.* Theoretically sutures passing through the skin and the deep tissues underneath are a menace to the patient, because they form a direct communication between the skin which contains staphylococci and the deep tissues which are primarily sterile; *b.* practically these stitches never cause an infection unless drawn too tightly, in which case the resulting pressure necrosis is the cause of the mischief, because it furnishes these micro-organisms dead tissue to thrive upon.

(5) *a.* Theoretically catgut sutures and ligatures are objectionable; *b.* practically, if applied properly and not tied too tightly by a clean surgeon with clean assistants, they are absolutely satisfactory and not objectionable.

(6) *a.* Theoretically, it is as safe to operate upon clean cases after dressing suppurating wounds as at any other time; *b.* practically, surgeons who follow this practice always have a great amount of wound infection on account of accidental contamination of something coming in contact with the wounds.

In order to have wounds heal without suppuration, he believes the following conditions should be considered:

(1) The surgeon, his assistants and nurses must be habitually clean, and the skin of their hands must be free from irritation and roughness.

(2) Their attention should constantly be directed towards the prevention of accidental infection.

(3) The surgeon and his assistants should be careful not to breathe or speak into the wounds.

(4) Tissues should not be exposed to unnecessary traumatism.

(5) Sutures should not be tied tightly enough to cause pressure necrosis.

(6) A reasonable system should be employed, so that everyone concerned can assist intelligently in preventing infection.

EXPANDED METAL A NEW SPLINT MATERIAL.

Hübscher[29] calls attention to this new building material as valuable and convenient for making splints. It can be made of any metal, as aluminum, and with metal shears is easily cut into any desired form. The open, lattice-like form of the metal makes it yield readily and conform to the contour of the limb, and yet when bound in place it is very rigid. In dressing a leg the foot piece is made by cutting the metal transversely nearly half its breadth on each side; it is then turned up along the sole of the foot, the cut ends interlocking into the leg portion of the lattice work. Angular splints of great rigidity are made in this way for any portion of the limbs or body. When combined with plaster-of-Paris this splint produces exceptional rigidity, and yet can be made much lighter than a splint made in the ordinary way of plaster.

PAIN AS A PATHOGNOMONIC SYMPTOM OF ECTOPIC PREGNANCY.

Coe,[30] in a paper read at a meeting of the Harvard Medical Society, January 27, 1900, summarizes his views as follows: Pain alone, when not accompanied by a clear history of menstrual irregularity, symptoms of pregnancy, and the presence of a tumor at the side of the uterus or in Douglas's pouch, known to be of recent development, is pathognomic of extra-uterine pregnancy only under certain conditions, namely: The pain is of a sharp, colicky character, distinctly localized on one side, attended with faintness more or less marked, and is usually followed by intervals of hours or days of complete remission. The pulse is accelerated during the attack, but there is no rise of temperature. The latter is an important symptom distinguishing ectopic from inflammatory conditions. The violent tearing pain attending intraperitoneal rupture is accompanied by the unmistakable evidences of internal hemorrhage. In extraperitoneal rupture the symptoms vary in severity according to the amount of blood lost, but soon subside, being succeeded by the usual evidences of pressure resulting from a mass in the folds of the broad ligament which displaces the pelvic organs. A persistent pain following the acute attack may indicate localized peritonitis.

[30] Medical News, April 21, 1900, p. 601.

A REMOVABLE DEEP SUTURE.

Schoemaker [31] describes a simple removable suture which overcomes the difficulties which have surrounded the employment of non-absorbable materials in uniting abdominal wounds layer by layer. It is nothing more nor less than the chain-stitch sewing of the older machines. A needle is employed having the eye in the point. It is carried through both sides of the wound and the loop caught. Without unthreading the needle it is withdrawn and the second stitch taken. This time, and on each successive stitch, the loop is carried through the last loop, thus locking it. The final stitch is carried out through the skin and the end pulled through the loop. When it is to be removed the end is withdrawn from the last loop by pulling on the thread, each successive loop is drawn out, and the whole thread is thus released. The thread can be drawn very tight without interfering with its removal, but rather facilitating it.

Regular meeting, April 17, 1901, Dr. V. Y. Bowditch in the chair.

Dr. S. A. Knopf, of New York, read a paper upon

MUNICIPAL CARE OF THE CONSUMPTIVE POOR.[1]

Dr. Knight: I certainly think we are very much indebted to Dr. Knopf for taking the trouble to come on here and help us out in our effort to make some headway, as I think we have already begun to do, against this great scourge. What Dr. Knopf has said certainly does not call for criticism, but only for commendation. I am very glad, however, to have this opportunity, after making a few comments on topics which he has suggested, to give my experience before our legislative body, particularly in behalf of the institutions for which I have appeared. Before I do that, however, I will say, in the first place, in regard to Dr. Knopf's statement that we have undertaken the most difficult task of all in setting up a hospital for the chronic cases, in undertaking to care for that class of consumptive patients, that this is true. It is a task of enormous magnitude and incapable of complete accomplishment. In the same way it seemed in the beginning, when the infectious character of the disease was first admitted, too big a problem to attack. But, although we cannot do at once all we strive for, we can accomplish a great deal, and that is very well shown in the statistics, particularly of German cities where they undertook the thing more seriously and earlier than we did. For instance, in Berlin in ten years after the adoption of very elementary regulations the mortality was diminished one-third. That is a tremendous gain. I don't believe the disease is going to be extinguished, but if we can make any such change in the mortality rate as that, it will be worth the undertaking.

Another thing has interested me very much. Dr. Knopf does not speak of it here, but does in his book. It pertains to the economic side of the problem, and that is the side which naturally, after the humanitarian, appeals to the legislator. He does not want to appropriate money too freely for the sake of humanity or of philanthropy, but if he finds the economic question favorably affected, he is all the more willing and ready. The point which I refer to is the experience of the insurance companies in Germany, the companies which insure the working people during sickness and make payments after death. These companies quite early became interested in the treatment of tuberculous cases, and began to put them into sanatoria, and they got them in so early that they obtained the best statistics as far as concerned shortness of stay required for cure; and they were so good that some of the companies, as Dr. Knopf states, have set up sanatoria for themselves, so that when their risks are infected with tuberculosis they have institutions in which they can put them for a few months or a year until cured, and then send them back to work. That is a good illustration of the economic value of these institutions for the treatment of the early cases.

In regard to the question of cure. I think we admit here in Boston the ultimate cure of many cases, but it takes a long time. If we should have an autopsy in arrested cases at the end of a year I don't think we would always call them cured by any means. With this idea of cure in mind we are possibly liable to make a mistake in returning cases of arrested disease too soon to their old occupations. I think we must be exceedingly careful about this.

Dr. Knopf speaks of the children. That is a very important point in the attack on the whole question, the treatment of children of consumptives. It is undoubtedly true, as he says, that a seashore home for them would save a very large percentage from developing tubercular disease in the future; so also is the treatment of the pregnant woman very important, a matter which has never

[31] Centrbl. f. Chir., April 7, 1900, No. 14; American Journal of the Medical Sciences, July, 1900.

[1] See page 487 of the Journal.

engaged our attention very much. And in regard to a commission, there is no question about its value. Just think how soon we would have had a commission if acute disease of such mortality had come upon us suddenly — yellow fever or any of those diseases which produce such scares — they would get a commission in a very short time; but this being chronic, we have become so used to it, that a commission never occurs to anybody. But a commission can do as much good or more in the treatment of a disease chronic in its nature as it can one that is acute.

When I first went to the legislature in regard to the sanatorium at Rutland the first thing that struck me was the willingness, apparently, of the committee to give us anything we wanted. The gentleman who had charge of the bill had no idea that he was going to get it through the first year. The finance committee, however, before whom that bill went, seemed to be unanimously in favor of it, and said to me: "You will eventually want more than one — two or three in different parts of the State?" I said: "Certainly, I think so." So it went through. And so it was the next year when we went up on some related question, and again this year, when we asked for a second sanatorium, the committee seemed fully alive to the importance of the matter. This has yet, however, to come before the finance committee. The committee, being business men, I think appreciated the economic as well as the humanitarian side of the question.

In our effort thus far to get a hospital for chronic cases in this city I think it is possible we made a mistake in designating the locality. It is possible if we had simply asked for an appropriation for that purpose and left the selection of site to a board of trustees afterward, it might have been better; but there had been so much talk this year about the expenditure of city money that it seemed rather improbable that we could get a large enough appropriation to build a suitable home, and so we looked around to see if the city owned any buildings which might be utilized without great expense, and we found the old Marcella Street Home in Roxbury which the city owned and apparently had no use for, and, after talking with the Mayor about it, it was understood if we asked for a building for that purpose he would recommend this one, which he did, but the recommendation failed to pass the council for various reasons, partly the opposition of neighbors, and very likely some members of the city government had other ideas in regard to the disposition of this building. There are some members of the city government here who will speak for themselves. I think, as far as I have heard anything about it, the feeling of the members of the city government is that we ought to have something of the kind, that if we ask for an appropriation for this purpose we will be likely to get something, and I hope what Dr. Knopf has said tonight will aid us in accomplishing that object.

DR. E. O. OTIS: I desire to express my appreciation of Dr. Knopf's kind service to us in coming here to give us the results of his most valuable and wide experience upon this all-important question. Surely no one, either in this country or in Europe, could speak with more authority. The whole civilized world is now aroused to the importance of stamping out consumption, and as evidence of this great movement is the coming "Congress on Tuberculosis," in London, under Royal auspices, a programme of which I have here and from which it will be seen that the subject of dealing with consumption is an enormous one.

The State and municipal authorities can and do now legitimately interfere in the matter of prevention. Consumption is a contagious disease, and the community have a right to demand of the authorities that all proper and known means should be employed to protect them from it. Further, as the municipality has assumed the duty of providing decent accommodations and proper medical care for the unfortunate sick poor, it can no longer ignore the large yearly contingent of poor consumptives who now are excluded from all the general hospitals. It is an unjust and cruel distinction of two equally worthy poor patients, to afford one all the benefits of our magnificent City Hospital because he is fortunate enough to have any other disease except consumption, and to relegate the other to the poorhouse because he is unfortunate enough to have consumption. I believe our city Board of Health has wisely put this disease in the list of contagious ones, and requires notification, as with the other contagious diseases; but as a logical result of this ordinance, the city must afford the Board of Health some means of isolating the poor consumptive when it finds he is endangering the lives of those about him. His honor, the mayor, and the honorable city council have taken this matter in hand, and already there is a bill before the city authorities for the appropriation of money to provide a city consumptive hospital. I believe that this will be in the process of accomplishment within the year. In a recent letter received from Dr. Briggs, of the Department of Health of New York City, he writes me that he hopes before the end of the present year to have in that city a consumptive hospital with a capacity of four or five hundred beds. I do not believe that Boston will be far behind New York. Dr. Knopf has elsewhere said that it is his firm conviction that for social and economic reasons the majority of tuberculous patients will have to be treated near their homes. In this opinion I concur, and all the more true is it because the majority of tuberculous patients are poor.

The district physicians of our Boston Dispensary are continually clamoring for some place to send their advanced cases of consumption, both that they may receive proper care and for the sake of the protection of the other members of the household. They will not go to the poorhouse because, from a natural pride, they do not want to die as paupers.

None of us believe that a city consumptive hospital will alone stamp out consumption — better

housing of the poor, better knowledge of how to live and take care of one's health, better sanitary conditions of workshop and store, more air spaces, playgrounds, sand-gardens, open air gymnasiums, fewer saloons, are all very essential factors in this great warfare against tuberculosis. Moreover, we must strive for a wide dissemination of the simple methods of avoiding the tendencies to consumption, and of safely disposing of the sputum of a consumptive.

Regarding the administration of a city consumptive hospital, I believe as Dr. Knopf does, that there should be as careful medical supervision of the patients as in the general hospitals, both in regard to the patients themselves and in order that there may be no possibility of danger to the neighborhood. As Dr. Knopf has shown, a properly supervised consumptive hospital is not only not a menace to the neighborhood, but on the contrary is a benefit to the community by serving as hygienic educators. As Dr. Knopf has said, "Well-conducted sanatoria for consumptives are not centres of infection, but, on the contrary, places where one is safest from contagion."

Another valuable aid in stamping out consumption is the especial ambulatory clinics for tuberculosis, such as now exist at the Boston Dispensary. Here one gets hold of the early cases, instructs the consumptive how to make the most of such environment in which he is obliged to live; how to keep from infecting others, and in many other ways such clinics are most valuable, not only in aiding the consumptive himself, but in protecting the community. Such especial clinics can from their nature, give more careful and prolonged attention to their patients than could be afforded in large general clinics. For example, during the first three months of this year there were 517 new patients at the tuberculosis clinic of the Boston Dispensary, and 1,120 new and old patients. Regarding State sanatoria I think we will all agree that Rutland has been and is of inestimable value, particularly in its educative influence. We shall soon have all over the State patients who have learned the plan of the open-air treatment and who, by example and precept, are teachers of others in wholesome methods of living, and who can show consumptives who cannot leave home how they can make the most of their home conditions. Patients from Rutland are now setting up boarding-houses in Rutland and elsewhere, where consumptives who cannot get into Rutland can go and carry out essentially the same plan of life and treatment as at the Sanatorium.

DR. A. K. STONE: I think we all thank Dr. Knopf for coming and giving us this talk, and also for the very flattering things he said about Boston and the State of Massachusetts. We are always glad to have the flattery, and we hope all he has prophesied will come to pass in the near future.

I was specially interested in what he had to say about the harmlessness of sanatoria. It is a subject to which the public must be educated. We have gone so far in our education of the public that consumption is a dangerous disease to those who come in contact with it, that we have almost produced the belief that a consumptive is a leper. It comes upon him in all directions. The poor man finds he is shut out from workshops and boarding-houses, avoided by friends, and in many ways his life is made very miserable. It seems to me we must swing the pendulum back and say the consumptive is not a dangerous person if he takes care of himself, lives in suitable surroundings, of which sanatoria are by far the most suitable. The medical man and the layman must all be taught that the properly constructed sanatoria are places where disease is held in check, not spread, and that the idea of the hypothetical bacillus that floats away from the walls or surroundings of a given sanatorium and is conveyed for half a mile's distance, is entirely hypothetical and must be disregarded. Even with a consumptive walking about the streets, expectorating on the sidewalk, the chances of the sputum being diluted, washed off, carried into the gutter, are very great, so that even in our dusty streets the amount of dilution is so much that probably the cases of infection from that source are very few in number; but when you come to cars, railway stations, and office buildings, where the material is confined, quickly powdered by the rapidly tramping feet into fine dust, there is a chance for infection; but it is not there even that the greatest chance lies, but in the home where the man is living in a small room, often with a carpet, there the chance of dust infection with him is very great. But where you come to the clean-painted walls, the hardwood floors, with care of himself and constant teaching in the care of his sputum and the general need of cleanliness, and the undesirableness of unnecessary coughing, immediately the disease is held in abeyance, and the chances of its spread are very, very slight. We want to emphasize this just as emphatically as we have emphasized the danger on the other side.

DR. MILLETT: I feel very keenly the compliment paid me in asking me to say a few words, quite as strongly as I feel my inability to speak on the subject. Dr. Knopf kindly mentioned our institution, and certainly after his able paper we must all of us keep very quiet. My own personal experience leads me to say a few words, however, about some of the subjects that have been mentioned. One is that the institution should be small. It seems to me it would be better if every county in the State had some such institution. Patients would be near their homes, could visit their homes when they began to get better, and would be much happier. Another idea is to tell the patient they contaminate themselves with the sputum if not extremely careful. This leads them to be still more cautious, and is kinder than to say they will poison other people. Dr. Otis spoke of the number of hours the patient should be out of doors. It is perfectly easy for a patient to be out of doors twenty out of twenty-four hours eight months of the year. In regard to cough, if they are out of doors eighteen to twenty hours a day

the cough almost wholly disappears and all the other symptoms are ameliorated.

DR. GERRY: I am very much pleased to be present tonight and to hear the discussion. I have been interested for a good many years in this matter of the prevention of the spread of tuberculosis. Two years ago, when I was president of the Norfolk District Medical Society, we tried to instruct the Boston Board of Health in regard to the prevention of tuberculosis, calling on them to fine people, etc., and we found that they had done that. Another idea we brought out was, that all rooms which were occupied by the consumptives, and in which consumptives died, should be just as thoroughly disinfected as those rooms in which people died from diphtheria, scarlet fever and typhoid fever.

I will not touch, particularly, upon the medical side of it, but I would like to say a word regarding the municipal side. There are, of course, a good many things to be considered when the city government begins to think about establishing a hospital, which necessarily must cost $100,000 to $300,000 in its building and be quite a large expense in the matter of maintenance. Those are the two things, as my friend Alderman Norris will tell you, that all committees of the city government have to consider. In the first place, we have the loan bill which comes in the finance committee, and another bill coming in the appropriation committee for maintenance, entirely separate and distinct, and one cannot encroach upon the other. I am happy to be able to say that I think that, not only the city government but the citizens of Boston are not only prepared to do what they can for the tuberculous poor, for their comfort, cure and the prevention of tuberculosis, but they are also desirous — the citizens are — that the city government should do something practical as soon as possible. I was very glad when this matter was brought up as it was in regard to the Marcella Street Home. I did not favor the Marcella Street Home as a hospital for the consumptives of this city. I opposed it because I did not consider it a proper place. It would be well enough if we could not have something better, but I was in hopes and am now, that we shall have something better. I felt that if the tuberculous poor of the city were turned into the Marcella Street Home we should never get any further, or not for many years. When you come to expend $40,000, as I believe the estimate was, for fixing up that old trap, we would have had to get the interest on the money before we could have moved to West Roxbury or Dorchester or any place better, hygienically and every other way. I think I can promise as much as anybody can promise who has to do with the voting of city money or getting votes enough for carrying a loan for any institution, that something will be done this year by the city government to see if we cannot relieve the tuberculous poor of the city of Boston, and put them in a place where they will not only get great benefit themselves, but cease to be a menace to their families and friends.

A remark was made by one of the gentlemen that we should not carry our tuberculous patients too far away from home. That is a very important point. Of course, it may be that the city of Boston may buy land and may establish a consumptives' retreat, we will call it, for the cure — I say for the cure — not only cure, but also, outside of the limits of Boston, the housing of chronics. I am one that believes that we can have two elements in this matter of a consumptive home; that is, properly treat the people who are amenable to cure, and also the people who are unfortunate and who are obliged to be victims of the disease. Now, we know that in our institutions for insanity, for instance, — Pierce Farm and the insane hospitals at Taunton, Worcester and other places, — the poor find it a burden to have the sick member of the family too far away. The car-fare is quite an item to the poor man. Then, again, it costs the poor man his day's labor when he goes to see his sick wife or one of his children. Of course, it is not quite as hard on the wife. I suppose the women do most of the visiting, but still the men like to go once in a while and see the sick friends, and the expense is, naturally, quite a little item; so that we find that Austin and Pierce Farms are very popular as places of retention and treatment of the insane, and made so largely by the fact that the friends of the insane can go there for ten or fifteen or twenty cents, on, perhaps, a holiday or Sunday, when they will not be exposed to losing their day's pay. I, occasionally, have applications from people who think their friends are going to be transferred from Pierce Farm to Taunton and wish them to be retained there, and state as the reason that it is so much handier to go there to see them. I am very glad that this matter is going to come up this year, because I want to take an active part in doing what I can to follow out the suggestions of my old teacher, Dr. Knight, and of the other medical gentlemen of Boston, whom I know very well, and I can assure you that we will do all that we can to secure the establishment of such an institution as you desire.

I agree with one of the gentlemen who said that instead of one large building, two smaller ones or more are better, if that plan can be carried out without too great an additional expense. If it cannot, we shall have to have larger buildings and do the best we can.

I am very glad of this opportunity to say my word, and I think you will be able to look to me to do what I can to help this matter forward.

MR. O'TOOLE: I do not know that there is much that I can say, speaking from the standpoint of a layman only whose interest lies in conquering as much as possible this disease, consumption. The first of this year I introduced an order in the city government for a municipal hospital for the care of incurable cases of consumption. The order asked for the loan of $400,000, and was referred to the finance committee. About the same time a committee, composed of the medical men of Boston, and I talked over the subject, and it

was proposed that we try to procure the Marcella Street Home for a consumptive hospital, and while I feel we may have made a mistake in so doing, I think our efforts were not wholly lost, for the educational work and the interest aroused through newspaper agitation were of great benefit to the community in enlightening them in reference to this disease. I feel, as a member of the city government, that this year we will get something in the way of a municipal hospital. Of course we may not be able to get a loan order of $300,000 or $400,000 through, on the plea of economy; but, inasmuch as the city government is thinking of appropriating $100,000 for a municipal zoo, I think it ought to be possible to get $200,000 or $300,000 for a municipal consumptive hospital. I will do all in my power to keep up the agitation, and feel it will result this year in something. I thank the gentlemen of the society for inviting me here tonight. I have been very much pleased and instructed by the paper read by Dr. Knopf.

Mr. Norris: I am here on the invitation of Councilman O'Toole, and I am glad I came. I was very much interested in listening to the discussion of the subject by the various medical gentlemen. Owing to the agitation of members of the Massachusetts Medical Society, with the cooperation of certain gentlemen connected with the city government, I think the chances of getting a consumptives' home in Boston are very good. I was pleased to hear the remarks of Dr. Gerry, who is associated with me on the finance committee. As chairman of that committee, I wish to say that when a meeting of that committee is called I shall be pleased to give a public hearing, and invite the members of the Massachusetts Medical Society to appear, in order to encourage the idea of a consumptives' home in Boston. I believe we should have such a home, but I believe in having it built within the limits of the city, so as to give the poor people of the city an opportunity to see their friends without expense and loss of time. I was at first in favor of using the Marcella Street Home as a consumptive hospital, but later I felt that were I a resident and abuttor on that place I possibly would object to having such an institution there. I believe it would be best to place it on some of the vacant land owned by the city. Our financial resources this year are large. We can borrow in the neighborhood of $6,000,000. Now I think Dr. Gerry ought easily to secure $200,000 of that for a consumptives' home, and I want to say to Dr. Gerry that I shall assist him in any way possible to secure enough money for that particular object.

I was very much interested in the paper read by Dr. Knopf, and I would like to see a copy of it when it is printed. This is a discussion which interests the home, the poor people whom I am pleased to represent. I know of cases which cannot be taken at Rutland because that hospital is already crowded. We have not a hospital in the city, except the Carney, which will take incurable cases of consumption. It is a shame, in my opinion. I am glad to see the Massachusetts Medical Society take this matter up. I believe that with your assistance and co-operation we shall be able this year to secure a consumptives' hospital. I thank you, Mr. Chairman, for inviting me to say a few words on this important subject.

Dr. Richards, of Fall River: I have come here tonight with three of my colleagues on account of the fame of Dr. Knopf and a little personal correspondence I have had with him from time to time, and because of the great interest that we, in the third city of this Commonwealth in point of population, have in this subject. We have been trying to do a little educational work in our city. We induced the mayor in his last annual address to suggest a municipal hospital. We are interested in the progress of Boston and other cities in this line; for we hope in our own municipality to be able to have some means of taking care of the consumptives. At present our chronic cases are admitted to our city hospital, which is an almshouse although a perfectly equipped hospital.

There is one point which has been a drawback, which no speaker has referred to, and that is the unwillingness of the patient in the early stages to accept the diagnosis of the physician, and also the unwillingness of many physicians to make the diagnosis, although pretty certain in their own mind that they have a case of tuberculosis to deal with. Furthermore, among many people, no sooner is a diagnosis of that kind made by a conscientious physician in the early stage of the disease than the patient promptly calls another physician. It has been said to me by a physician of ability that he could not afford to make such a diagnosis, because if he did so he immediately lost his patient, so that he must call it bronchitis, etc., and do the best he could until such time as the disease had advanced sufficiently to be evident to any one. We have a campaign of education to make among the profession as well as among the laity. There can be no doubt of the laity being scared. I visited Rutland and Princeton last summer, and the gentleman who drove me around told me that people from New York and Boston, summer residents, were afraid to drive within two miles of the Rutland Sanitarium for fear of being infected. I was told by a physician in the town of Princeton that the idea suggested itself to him of having a sanitarium in Princeton, but he said if he did he would lose all his other practice. No tuberculosis patient will be admitted in any private boarding house or hotel. The summer residents of the town of Princeton are scared on account of the proximity of the town of Rutland, and afraid of great depreciation of property on account of the nearness of Rutland.

We are having the same trouble as others with reference to sending patients to Rutland. A few years ago we could not get the patients to go, and now they are returned because there is no

room. I was afraid possibly it was because we were away from Boston, and did not have any pull, and I wrote Dr. Bowditch that we were afraid that we were being discriminated against; but he replied that we were not; it was the same from every quarter. Massachusetts is doing a tremendous amount of good along this line, and such meetings as this do good because reported elsewhere. A little pamphlet of mine on the "Duty of the State towards the Tuberculous" was used this year before the legislature of Minnesota, and a physician in St. Paul wrote me that they had secured the appropriation for the land, and hoped next year to get the building.

DR. FAIRBANKS: I would like to relate one case to illustrate the utter impossibility of treating these poor people in their homes. A woman came some time ago with moderate trouble in the lungs, and we put her through the usual course of instruction. She had no appetite, and we put her on a bitter tonic. She came back in the course of a week, saying her appetite was better, and went away again, and that kept up three or four weeks, yet she did not gain, was steadily losing, but each time she said her appetite was better. On inquiring more thoroughly into her circumstances, with reluctance, she admitted that some days she got scarcely anything to eat. It was absurd to give that woman a tonic for her appetite when she had not anything to eat. She informed us that her husband had died some months previously of the same disease and she had nursed him. All the funds had gone. There were two children in the family. Two weeks ago an Italian woman came with incipient trouble in one lung; she had six children, the oldest eight and the youngest under a year. She could not speak English. It was almost impossible to talk to her, to advise precautions; practically a hopeless case. We could do nothing to save those children from the great danger to which they were exposed. It is the matter of food, which is the greatest difficulty. We may give these people a good appetite, but cannot furnish the food to satisfy it.

The educational value of these people who come from a sanitarium, particularly from Rutland, is great. I have had occasion to examine several who have come simply to have their lungs examined. It is remarkable to compare them with the ordinary case from the city homes. I have sometimes felt perfectly helpless in dealing with these latter people. I do not know what to do. All cases of evident trouble are reported to the city. All they do is to visit the case, keep track of it until death occurs, when they disinfect.

DR. V. T. BOWDITCH: The object of this meeting was to give a special impetus to the efforts made lately by some of our colleagues and a few of the laity towards establishing a municipal hospital for the consumptive poor, more especially for the advanced cases who are known to be too ill to receive permanent benefit from sanitarium treatment.

It is especially gratifying to hear of the cordial endorsement which the scheme has received, not only from the mayor, but from influential members of the board of aldermen and common council. Whatever decision is finally made as to location, it shows us at least that we have hope for the establishment in the near future of a suitable institution in or very near Boston. No one could possibly realize more than myself the crying need which exists here for proper shelter for the hopelessly ill consumptive. In my connection with the Sharon Sanitarium and the State Sanitarium at Rutland I am constantly brought face to face with these poor people for whom there exists no adequate provision, and the pathos of it cannot be too strongly painted.

Our hands are tied in trying to give these poor people advice. If we tell them to try to get into the country, we find that the doors of boarding houses are becoming more and more tightly closed against them, as the idea of the communicability of the disease becomes more and more an established idea in the minds of the community. We need say nothing at this time of the instances of heartless cruelty on this point which must come to the attention of every physician who has had any experience with such cases. Surely it is our duty to provide adequate shelter and treatment for these poor people without delay.

I can add nothing to what has been so well said here this evening. I only wish to emphasize most heartily what Dr. Otis has said in regard to the possible marked improvement of some patients sufficient to warrant their transfer to a sanitarium for the more hopeful cases. I claim that no physician can speak positively as to the future of any consumptive from one examination. Surprising cases of improvement with proper care we all see, and we should adopt no name for such a hospital which would seem to take away hope from those who enter it. While I believe its purpose should be primarily to receive the advanced cases of consumption, under no condition whatever should it be called a hospital for incurables.

I wish to add my thanks and express my sense of personal obligation to Dr. Knopf, who, at much sacrifice of time, has given us his valuable and helpful paper this evening.

DR. KNOPF, in closing the discussion, said: My eminent colleague, Dr. Knight, did not quite agree with me on the expression "absolute cure." In a little work I recently published,[2] I quoted the following statistics which give an idea of the relative duration of cures of consumptives. These statistics are of recent date: Among 99 patients discharged from the Falkenstein Sanatorium as cured, 72 were well at the time the inquiry was made, which was three to nine years after the patient had left the sanatorium. In 15 cases a relapse had occurred, but 12 of these patients had improved again; 12 of the 99 had died. Dr. Wolff's inquiries concerning 95 patients discharged as cured from Brehmer's institution in Gœrbersdorf, resulted in the following: Five were alive

[2] American Edition of the International Prize Essay, Tuberculosis as a Disease of the Masses and How to Combat It. M. Firestack, 200 West 96th Street, New York: Publisher.

and well after a period of from twenty-one to twenty-nine years; 52 were well after a period of from twelve to twenty-one years; and 38 were well after a period of from seven to twelve years. Dr. Hauffe, of the St. Blasien Sanatorium in Germany, wrote in 1891 to 324 former patients who had left the institution between 1879 and 1889. Forty-six did not reply, 5 were reported dead, 12 had grown worse, 201 thought themselves still relatively cured, and 72 were absolutely cured. Dr. von Ruck, of Asheville, N. C., reported to the author of this essay that he had written to 650 of his former patients who had left the sanatorium from one to three years before; 457 responded, directly or through friends. Of these, 67 felt absolutely cured; 70 felt relatively cured; 258 felt still improved; 62 got worse or had died. Dr. E. R. Baldwin, of Saranac Lake, N. Y., reported recently that at the Adirondack Cottage Sanatorium they were in constant correspondence with 115 patients who had been discharged within the last ten or twelve years, and while a few had relapsed slightly, the majority were well at their homes. Of course these reports do not, and cannot, correspond exactly. With the exception of the last-named institution, which only takes patients in the earlier stages, those sanatoria receive patients for treatment in all stages of the disease. But, as a whole, these statistics are certainly encouraging, and the question, "Can consumption be absolutely cured?" may well be answered in the affirmative. Of course, in regard to patients discharged from a sanatorium as cured or improved, there remains a most important work to be done to help the solution of the tuberculosis problem. We must keep the patient who is discharged from the sanatorium under control, and it was for this reason that I pleaded with you to have a special institution in the city, a reception hospital with a dispensary attached to it, where a patient who had been in the sanatorium could go in case of a relapse, and ask new advice if his improvement does not continue.

I was exceedingly pleased by the favorable comments made by several of the gentlemen on home climate. I believe that the majority of consumptive patients, and the majority of them are poor, should be treated in a climate as nearly as possible the same as that in which they will have to live and work after their restoration to health. If you send a patient away to a very high altitude where different climatic conditions prevail, his chances of remaining well after his return to lowlands may be considerably diminished. But let it be understood that, no matter to what climate the patient may be sent, he must be treated and not be kept. And here I cannot emphasize enough what has already been said so well by my distinguished friend, Dr. Otis, that a so-called "consumptive home" without a residing medical officer to supervise and treat the inmates, can not be considered an up-to-date institution, intended to combat tuberculosis. To see that fifty or a hundred consumptive patients never violate any of the rules concerning the care of the infectious sputum, requires more than the gentle hand of a minister or matron, the persons usually selected as managers of consumptive homes.

One of your distinguished aldermen spoke of the necessity of having the institutions near the city, saying that the relatives of the patient would be often very anxious to see him. This is true, but there is another point which I believe to be just as important: We should not send the majority of patients far away, because we must avoid adding to their sufferings another disease, namely, nostalgia, or, in other words, homesickness.

We should not make people afraid of consumptives. While we should always teach the danger and the communicability of the disease, we should not call it contagious in the sense of being conveyed from the consumptive to the healthy person by simple touch. Some people are afraid to shake hands with a consumptive. A clean consumptive is no more a danger to his fellowmen than any healthy person, and I am far more willing to go and sleep in sanatoria and in the homes of careful consumptives than in many other places. I have lived for months in sanatoria with consumptive patients, taken my meals with them, and slept in rooms previously occupied by some of them, and I felt more sure that I would not catch consumption than I feel in some of our Pullman sleepers.

Time is passing, and much as I would like to say a few words in response to everyone who has honored me by discussing my paper, I must stop. I wish to thank them and you all for so kindly listening to me. I hope we will ere long have such good and generous aldermen in New York and such a wise city and State government as you have. Then we, too, will have all the institutions we need. Let me congratulate you on the really remarkable help you receive from your city fathers, and I wish to repeat what I said in my paper that I believe Boston and the State of Massachusetts will be the first places in the Union where the tuberculosis problem will be solved.

Recent Literature.

Sexual Debility in Man. By F. R. Sturgis, M.D., formerly Clinical Professor of Venereal Diseases of the University of the City of New York; sometime Visiting Surgeon to the Venereal Division of the Charity Hospital, Blackwell's Island, etc. New York: E. B. Treat & Co. 1900.

If originality is lacking anywhere in this work it is certainly not in its dedication, in which the writer expresses a somewhat singular sentiment in the following words: "To the sexual cripples of the United States, whose infirmities have in part contributed to his support, this book is gratefully dedicated by their obliged friend, the author." It is to be hoped that the cripples will appreciate this handsome acknowledgment; the profession may perhaps be excused for failing to do so.

After this unusual prelude there is a sense of disappointment upon finding that the work must be ranked as but one of a series, already too numerous, we believe, of similar publications, since it has not the distinction of especial excellence. It is well arranged, and the sequence of its subjects is good. The nine illustrations which appear at the end of the volume are rather inferior in quality. In the chapters devoted to the anatomy and physiology of the male sexual organs there are some interesting examples of abnormal and precocious sexual development recorded, but as a whole this part of the work adds nothing new of scientific or practical value to our present knowledge of the subjects. The chapter in which masturbation is discussed is notable chiefly for the expression of the writer's view of the subject, which combats the usually accepted belief as to the serious evils resulting from indulgence in the habit, and condemns that idea as exaggerated and mistaken, unless the habit is practised to excess such as is infrequently met with. While conceding to this work some good qualities, we do not think that it is entitled to special consideration, or that it has the merit which we might expect in a contribution from this author.

A Dictionary of Medical Science. Containing a full explanation of the various subjects and terms of anatomy, physiology, medical chemistry, pharmacy, pharmacology, therapeutics, medicine, hygiene, dietetics, pathology, bacteriology, surgery, ophthalmology, otology, laryngology, dermatology, gynecology, obstetrics, pediatrics, medical jurisprudence, dentistry, veterinary science, etc. By ROBLEY DUNGLISON, M.D., LL.D., late Professor of Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College. Twenty-second edition, with appendix, thoroughly revised and greatly enlarged, and with the Pronounciation, Accentuation and Derivation of the Terms. By ROBLEY J. DUNGLISON, A.M., M.D. Philadelphia and New York: Lea Brothers & Co., 1900.

In the preface, the present editor tells us that "more than seventy years have passed since Dr. Robley Dunglison gave to the English-speaking world its first standard of medical lexicography, during which long period no less than twenty-one editions have been called for, and it is a fitting and proper tribute to his memory that the author's portrait should preface the twenty-second revision." As illustrating the growth of the many sciences embraced today in the word medicine, and the difficult task imposed upon the medical lexicographer, the preface also tells us that the twentieth edition contained 6,000 new words, the twenty-first edition, issued seven years ago, increased by 44,000; a few years later 2,000 more were added, and now in the present edition 15,000 words are added.

Dunglison's Medical Dictionary has been too long and too favorably known by the medical profession to need further endorsement at this day, beyond the statement that this new edition puts it well abreast of the times.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 23, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

NEW LIGHT ON THE CAUSE OF PANCREATITIS.

AT the recent meeting of the Association of American Physicians, no more valuable or original work was presented than that embodying the researches of Dr. E. L. Opie concerning the etiology of acute hemorrhagic pancreatitis. The suggestion for the experimental investigation carried out by Opie was given by the following case:

A patient ill with acute abdominal symptoms was operated upon, and acute hemorrhagic pancreatitis discovered. No gall stones were felt during the operation, although they were searched for carefully; but at the autopsy, which occurred soon after, a biliary calculus was found in the diverticulum of Vater, occluding the entrance of the conjoined pancreatic and hepatic ducts into the duodenum. The stone was only a few millimetres in diameter, and had naturally enough escaped detection at the operation. It was of sufficient size, however, completely to prevent the entrance of bile into the duodenum, so as to shunt off the bile stream into the pancreatic duct, and an extensive infiltration of the pancreas with bile was noted at the autopsy. The possibility occurred to Opie that the pancreatitis might be due to the soaking of the pancreas with the misdirected bile stream, and he accordingly instituted experiments upon dogs, to determine whether hemorrhagic pancreatitis could be produced by the injection of the animal's own bile into the pancreatic duct.

The result of these experiments was the demonstration that the lesions of acute hemorrhagic pancreatitis, both gross and microscopic, can be produced experimentally by the injection of bile. These experiments also show that even a very temporary biliary obstruction by a gall stone in the diverticulum of Vater might suffice to produce pancreatitis. On reviewing the literature relating to autopsies in cases of acute pancrea-

titis, Opie found that in almost all fully described cases the presence of gall stones in some part of the biliary tract was noticed. If gall stones are present at autopsy in all cases of pancreatitis and if the presence of bile in the pancreas is sufficient to excite experimental pancreatitis the presumption is strong that misdirected bile is the *fons et origo mali*. It is not essential that the calculus should be in the diverticulum of Vater at the time of autopsy. It may have lodged there but a few minutes, temporarily diverted the bile into the pancreas, and then passed on. We have, then, a plausible explanation of the cause of acute pancreatitis, and while it is not yet safe to say that the only cause of acute pancreatitis is the deluging of the pancreas with bile, yet it certainly seems justifiable to consider that many cases are brought about in this way.

In the course of the same discussion, Flexner demonstrated specimens of acute experimental pancreatitis produced by the injection of gastric juice into the pancreas. He admitted, however, that it seemed very unlikely that gastric juice would find its way into the pancreas.

Two comments upon Dr. Opie's discovery will occur to everyone: First, that cancer of the duodenal papilla or pancreatic stones lodging in the diverticulum of Vater might cause a similar turning of the bile stream into the pancreas. Secondly, that catarrhal jaundice, were its pathology as generally stated, would be apt to be followed by acute pancreatitis. The time-honored hypothesis of the mucous plug at or near the duodenal opening of the pancreatic and hepatic ducts, in cases of catarrhal jaundice, has been doubted by many pathologists. We are not here concerned with the truth of this hypothesis, but desire only to point out that, if it were true, the gastro-duodenal catarrh, which we ordinarily picture as extending to and occluding the lower biliary passages, might occlude, *first*, the duodenal opening of the conjoined ducts and so turn the bile stream into the pancreas. If, then, the old explanation of catarrhal jaundice were held to, it would seem strange that hemorrhagic pancreatitis does not oftener follow. To us, however, it seems more likely that Opie's discovery will tend to throw still greater doubt upon the "mucous plug" theory of catarrhal jaundice.

No doubt these points will be considered by Opie in the printed text of his paper, no abstract or summary of which has yet found its way into any of the reports of the meeting at which it was read — a curious, perhaps an inspired, omission.

In conclusion, we desire very heartily to congratulate Dr. Opie upon the completion of one of the most interesting and valuable pieces of scientific work yet done in America.

A NEW MEDICAL LABORATORY FOR THE UNIVERSITY OF PENNSYLVANIA.

WITH the development of medical education, which has marked the last few years, has come the necessity of providing space for the prosecution of the work which is both an effect and a cause of that development. The medical school of the future clearly cannot be contained in one small building, provided with several lecture rooms and an occasional laboratory. Above all things, room is required, not only for original investigators, but also for the use of students. It is perfectly safe to say that nearly every medical school in America is more or less hampered in its teaching facilities by this lack of adequate space for the practical work of its students. It is also a safe prophesy to make that the next few years will see an extraordinary growth of buildings devoted to medical science in the broad sense.

The University of Pennsylvania seems likely to be a pioneer in this effort to enlarge the possibilities of a truly liberal medical education. We have before us plans of a proposed laboratory building, to be erected at a cost of upward of $500,000, for the medical department of that university, with other detached buildings in contemplation. The announcement of the general plan of the new building states that it will be two stories in height above a high basement, and will measure 340 feet front by nearly 200 feet in depth. The long front faces north, securing a maximum amount of the best light for laboratory purposes. Along the front are arranged small rooms for research, rooms for professors and their assistants, a library, etc.; these open into a private corridor, so that men employed in these rooms may pursue their work without interruption from students passing through the main halls. The first floor will be devoted to physiology and pharmaco-dynamics, and the second floor exclusively to pathology. Special laboratories will be provided on this floor for comparative pathology, neuro-pathology and surgical pathology, with abundant rooms for individual research. In addition to these laboratories there are to be four lecture rooms, two with a capacity of 185 students and two with a seating capacity of 400. In the construction of the building care has been taken to provide sufficient light, a matter which at times is overlooked; a large central court admits direct light to the inner portions of the various laboratories. Ample provision has likewise been made for photography, which has become an essential adjunct of the modern laboratory.

This step in progress on the part of the University of Pennsylvania should prove a stimulus to many other institutions. While recognizing the fact that buildings and laboratories do not make a

medical school, nor necessarily develop investigators and scholars, we are, nevertheless, convinced that such a material recognition of the needs of medical instruction will do much to bring nearer the day when medicine will be completely established as a branch of scientific education.

THE ILLEGAL SALE OF NARCOTICS.

A SOMEWHAT alarming report comes from Vermont as to the amount of narcotic drugs sold and consumed in that State. The following is said to be in part the substance of an investigation recently instituted by Dr. A. P. Grinnell, of Burlington: "In the regular drug stores and in 160 of the 172 general stores in the State of Vermont there is sold every month 3,300,000 doses of opium beside what is dispensed in patent medicines, and beside what the doctors dispense, which gives one and one-half doses of opium to every man and woman in the State above the age of twenty-one years every day of the year. By dose I mean one grain opium, one-eighth grain morphine, one-half ounce paregoric, and twenty drops laudanum. The amount consumed each month means a half-dose for every person in the State every day of the year."

Whether or not these figures are exact, we have no means of knowing, but in any case the result of Doctor Grinnell's investigation gives us considerable food for thought. The one palpable fact of importance which we must all recognize is that drugs are sold illegally in large amounts everywhere and that no adequate measures are taken to stop the traffic. It is a common enough experience to be told by morphine habitués that they have no difficulty whatever in obtaining the drug in as large an amount as they desire. There apparently exists in certain instances a kind of freemasonry between the buyers and sellers which naturally does much to extend the evil. On one occasion a young woman who was on the verge of a complete breakdown from morphine-taking and other vicious habits, told us, with considerable resentment, that of course she would not tell where she got her drugs; that they had treated her squarely in selling to her, and that she had not the smallest intention of "giving them away." Doctor Grinnell has certainly inaugurated a good work and one which should ultimately be of great value to the community at large, if he can succeed in exposing the full extent of the vice in his State and can further accomplish the more difficult task of bringing to justice the men who profit by the illegal business.

In connection with this general subject, a recent decision of Judge Cornish, of Lewiston, Me., regarding certain proprietary medicines, is of importance and interest. The litigation arose from an attempt to bring into the State a certain so-called medicine containing a large amount of alcohol. The Judge, in rendering his decision, said: "The testimony shows that wine is the predominating element in this compound; that it contains 23% of alcohol; that the wine retains its character as an intoxicating liquor, capable of use as an intoxicating beverage, notwithstanding other ingredients have been mixed therewith. The compound, therefore, falls under the ban of the law."

This, again, is undoubtedly a step in the right direction. It is extremely desirable that people in general be made aware of the ingredients of the numerous nostrums, which are paraded as specifics before the public. There can be little question that various addictions are fostered, if not actually started, by so-called specifics, the ingredients of which are unknown. The whole problem is a large one, and one, no doubt, exceedingly difficult of satisfactory solution, but a little energy on the part of the constituted authorities, and a stricter censorship of drug concerns on the part of physicians, would certainly do much to mitigate the evil.

MEDICAL NOTES.

OFFICERS OF AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION.— The following officers were elected at the annual meeting of the American Gastro-Enterological Association held in Washington, D. C., May 1, 1901: President, John C. Hemmeter, M.D., Baltimore; First Vice President, W. D. Booker, M.D., Baltimore; Second Vice President, S. J. Meltzer, M.D., New York; Secretary and Treasurer, Charles D. Aaron, M.D., Detroit. The next annual meeting of the Association will be held in Washington, D. C., May 2, 1902.

DEATH OF JOSEPH FODOR, M.D.— Joseph Fodor, M.D., professor of hygiene at the University of Budapest, has died. He was born in 1843, was a pupil of Pettenkofer at Munich, and later studied under Baron Liebig.

A DECORATION FOR DR. CHRISTIAN FENGER.— Dr. Christian Fenger, of Chicago, has received the Cross of Dannebrog from King Christian IX, of Denmark, in recognition of his contribution to surgical knowledge.

SMALLPOX IN DETROIT, MICH.— A number of cases of smallpox have recently been discovered in a Polish convent in Detroit. The institution has been quarantined by the Board of Health.

SPECIAL TRAIN FOR THE AMERICAN MEDICAL ASSOCIATION.— Arrangements have been perfected with the Chicago & Northwestern Railway, to run a special train from Chicago to St. Paul for the

accommodation of such members of the American Medical Association and their friends as desire to attend the fifty-second annual meeting.

A Negro Centenarian.—Rev. William H. Connor died recently at his home in New London, Conn., aged nearly one hundred and one years. He was born in slavery.

Stanford E. Chaille, LL.D.—Tulane University, New Orleans, has recently conferred the degree of LL.D. on Dr. Stanford E. Chaille, dean of the medical department.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, May 22, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 60, scarlatina 35, measles 150, typhoid fever 8, smallpox 13.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending May 18th was 193, as against 245 the corresponding week last year, showing a decrease of 52 deaths, and making the death rate for the week 17.9. Consumption 27, pneumonia 26, whooping cough 0, heart disease 16, bronchitis 5, marasmus 3. There were 5 deaths from violent causes. The number of children who died under one year was 31; under five years, 54; persons more than sixty years of age, 44; deaths in public institutions, 67.

Smallpox in and about Boston.— Several cases of mild smallpox have come to light in Roxbury. It is said that 3,000 persons have been vaccinated in the district in which the disease has appeared, and no serious epidemic is apprehended. A single case of smallpox is also under treatment at the United States Marine Hospital in Chelsea, having been transferred from a vessel coming from New York. Isolation is complete and there is no likelihood of the development of other cases.

Examination for License to Practice Medicine in New Hampshire.— The next examination for licenses to practice medicine in the State of New Hampshire will be held at the State House, Concord, on Tuesday and Wednesday, June 11 and 12, 1901, beginning at 8 o'clock A.M. All unlicensed physicians who were not in practice in this State on and before March 16, 1897, must pass the examinations in order to receive a license to practice legally their profession.

A Centenarian. — Mrs. Eunice Slade died in Walpole, N. H., May 12th, at the age of one hundred and one years and six months. She was married before she was twenty, and is survived by 2 children, 15 grandchildren and 13 great-grandchildren.

Bequest to the Carney Hospital.—By the will of the late Julius Adams the Carney Hospital is to receive $56,500.

NEW YORK.

Opening of Hospital for Crippled and Deformed Children. — The formal opening of the New York State Hospital for the Care of Crippled and Deformed Children, at Tarrytown, took place under the most gratifying auspices on May 17th. The establishment of the hospital is due, mainly, to the efforts of Dr. Newton M. Shaffer, now its surgeon-in-chief, who, in a paper on "The Care of Crippled and Deformed Children," read at the annual meeting of the National Conference of Charities and Correction held in May, 1898, spoke of the large number of these unfortunates who were being only half cared for by the existing medical institutions of the State, and aroused interest in the subject. Later, a bill incorporating a State hospital for this class of patients was passed by the legislature and an appropriation for it of $15,000 for the first year was made. In June of last year, an old country house on the banks of the Hudson, at Tarrytown, with spacious and attractive grounds, was leased, and has since been renovated and equipped for hospital purposes at an expense of $5,000.

American Congress of Tuberculosis. — The second annual Congress of Tuberculosis was held at the Hotel Majestic on May 15th and 16th, under the auspices of the New York Medico-Legal Society. The election resulted in the selection of Dr. A. N. Bell, of New York, former President, as Honorary President; Dr. Henry Holton, of Vermont, as President; and Clark Bell, Esq., of New York, President of the Medico-Legal Society, as Secretary and Treasurer. A long list of vice presidents was also elected. The aims of the congress, as announced, were: First, to determine the best methods for checking the spread of consumption; and, second, to recommend legislation for carrying the same into practical effect. It cannot be said, however, that the cause of scientific medicine was advanced to any appreciable extent by the meeting. No discrimination, whatever, seems to have been shown in the selection of papers, so that the time of the convention was largely taken up by cranks and by those with axes to grind in the shape of self-lauded special methods of treatment.

Appointment of Dr. Frederick Peterson.— Governor Odell has made an admirable selection in the appointment of Dr. Frederick Peterson, of New York, on the State Commission in Lunacy, in the place of Dr. Wise, which was announced on May 13th. In addition to having made spe-

cial studies in Europe, comprising six years in all, Dr. Peterson was for three years first assistant physician in the Hudson River State Hospital for the Insane. He has had a large experience as a private consultant, and is at present president of the Craig Colony for Epileptics, consulting physician to the Manhattan State Hospital for the Insane and clinical lecturer on insanity in the medical department of Columbia University.

SMALLPOX. — In consequence of the considerable number of cases of smallpox occurring among immigrants arriving from Naples, Health Officer Doty recently held a conference with the various steamship companies trading to that city, in which the companies agreed to at once notify their agents abroad to use their best efforts to secure the rigid enforcement of the regulations regarding smallpox and vaccination.

Miscellany.

THE ONE HUNDRED AND FIFTIETH ANNIVERSARY OF THE PENNSYLVANIA HOSPITAL.

THE exercises commemorating the one hundred and fiftieth anniversary of the founding of the "Mother of American Hospitals" were held in the new entrance hall of the hospital May 11th. Among the guests were many American physicians and not a few representatives of foreign societies and medical associations.

The address of welcome was delivered by the president of the Board of Managers, Benjamin H. Shoemaker. He spoke briefly of the first action taken to found the hospital, and introduced as the speaker of the occasion Mr. John B. Garrett, a member of the Board of Managers, who delivered the commemorative address. This was historical in character, the progress of the hospital being traced from its inception to the present time. At the time of its foundation the province of Pennsylvania had a population of about 200,000, and the city of Philadelphia 25,000. It was remarkable that less than seventy years after Penn's treaty with the Indians and twenty-five years before the Declaration of Independence was signed, an institution for the care of the sick should be established, and, what was more remarkable for those times, that it should include provision for the insane. Benjamin Franklin was largely responsible for the inception of the institution, but his name is not prominently identified with its early history.

May 11, 1751, the act incorporating the "Contributors to the Pennsylvania Hospital" was signed by Governor Hamilton, and from that day the institution dates its history. In August of the same year subscriptions to the amount of £2,751 were reported, this making available £2,000 voted by the Assembly. In 1754 the lot of ground on Pine Street, from Eighth to Ninth, on which the hospital now stands, was purchased. In 1755 the cornerstone of the new hospital was laid.

The founding of the insane department marked a distinct epoch in the history of the hospital. A partial separation of the insane and of the sexes was begun in 1825, but the accommodations were inadequate. In 1835 a tract of 101 acres was purchased in West Philadelphia, buildings erected, and in 1841 the insane patients were removed thereto. Drs. Rush and Physick took charge of cases, and thus took a distinct step in the specializing of medicine. This period also marks the beginning of a distinct advance in the treatment of the insane, and in the results attained. The history of the insane department has been one of constant advance.

The Pennsylvania Hospital has received no State or municipal aid for over a century.

After the commemorative exercises were over the visitors made an inspection of the hospital buildings. A like inspection of the insane department was made May 18th.— *American Medicine.*

THE SUBSIDY PROBLEM IN NEW YORK CITY.

ON May 13th, when the general session of the National Conference of Charities and Correction, convened at Washington, was devoted to a discussion of the division of work between public and private charity, Controller Color, of New York, made an interesting and instructive address on the subsidy problem in that city. In the course of it he said: Largely on account of the constant afflux of an alien population, the charity problem of no other city of the world can be compared with that of New York. Prior to the passage of the so-called Stranahan Act in 1899, the city had been appropriating various sums of money to private charitable institutions, under special acts of the legislature, passed from time to time, at the solicitation of individuals interested in these institutions. No uniform policy had been pursued in the passage of these acts. The whole subsidy system was characterized by an entire lack of system. The effect of the Stranahan Act of 1899, following the Constitutional amendment of 1894, was to grant to the local authorities full and ample power and discretion in the matter of making appropriations for charitable purposes, and to throw upon the city government the entire responsibility for these expenditures. In rearranging and reapportioning appropriations for private charities in the budget of 1900, the Board of Estimate and Apportionment adopted the following principles: First, all such appropriations were included in the annual budget, which is raised directly by taxation, so that each item thereof could be under the easy scrutiny of the taxpayers.

Secondly, with scarcely an exception all payments to private charitable institutions were measured by a system of per capita charges or by

some other system of pro rata payments governed by the specific service performed.

In 1899 the amount actually expended by the city in aid of private charities was $2,886,229.30. Under the new system first inaugurated in 1900, the Board of Estimate and Apportionment appropriated $3,079,259.60,—it being uncertain at the time of making these appropriations just what the results of the new system would be. The actual amount expended in 1900, however, was $2,676,534.28, or $200,695.02 less than the amount expended in the preceding year, and $402,725.32 less than the amount appropriated. Speaking broadly, therefore, I may conclude by saying that the subsidy system of New York City has been greatly improved by entrusting its treatment exclusively to the local authorities, and that while it is still a proper subject for much criticism and improvement, there has been enough accomplished already to mark out a path upon which the most substantial and beneficial progress may be made in the future.

THE FACTS ABOUT A TYPHOID FEVER EPIDEMIC.

IN the April *Monthly Bulletin* of the Connecticut State Board of Health, Dr. C. A. Lindsley, secretary of the Board, makes the following authoritative statement regarding the recent outbreak of typhoid fever in New Haven:

On the 3d of April, 1901, 6 cases of typhoid were reported to the health officer, all in one section of the city. This was indicative of a fresh localized infection which threatened further results. An investigation was begun at once with such success that on the following day it was discovered that one reservoir, supplying the section of the city in which the fever patients resided, had become infected from a family living on its watershed. The water was immediately shut off from its consumers, and has not since been used. New cases continued to be reported daily in increasing numbers until the 9th of April, on which day 95 were reported. From that date the numbers gradually diminished until near the end of the month, when they ceased. This termination of the outbreak was expected, as the period of incubation after the 4th of April had expired. During April, between the 3d and the 30th, 455 cases were reported at the office of the Board of Health. Some of these were reported as "suspicious," and others were prematurely stated to be typhoid but which afterwards proved not to be. A careful inquiry is being made to determine as close as possible the number of true cases.

The total deaths at this date, May 12th, have been 54, nearly 12% of the cases reported. The reservoir has been emptied completely and the pipes flushed with water from other sources. The reservoir has been refilled and will stand, by order of the Board of Health, unused a month and then drawn off, and may again be refilled for renewed use.

The New Haven Water Company, under its present management, has been and is making many efforts to protect the water from contamination. Many hundred acres of watershed have been purchased and cleared of all sources of pollution. The large extent of watershed contributing to the supply is constantly patrolled. The town health officers are paid for reporting to the company every case of typhoid fever occurring near any tributary to the reservoir.

Notwithstanding all the above precautions, this disastrous accident has occurred, and illustrates, more emphatically than any argument, the danger of disposing of typhoid excretions without previous disinfection.

Obituary.

CHARLES RICE, PH. D.

CHARLES RICE, PH. D., for thirty-five years a chemist in the Department of Charities of New York City, and one of the leading pharmaceutical authorities in the country, died at Bellevue Hospital on May 14th, of cancer of the throat. He was born at Munich, Bavaria, in 1841, of Austrian parents, and was educated at Munich, Vienna and Passau. He came to America in 1862, and served as surgeon's steward in the navy until 1865, when he entered the service of the Department of Charities and Correction, New York. In 1867 he was made a trustee of the New York College of Pharmacy, and afterwards served as chairman of the Pharmacopœia Committee of the American Pharmaceutical Association, and also chairman of the National Commission on Revision of the United States Pharmacopœia. He received the honorary degree of Doctor of Philosophy, from the University of the City of New York, and was an Honorary Fellow of the New York Academy of Medicine, and an Honorary Member of the Philadelphia College of Pharmacy. In addition to his professional attainments, Dr. Rice was eminent as an Oriental scholar, doing valuable work for the Indian Government, and was recognized as an authority in philology and etymology. A special meeting of the medical board and staff of Bellevue Hospital was held to take action on his death.

RECORD OF MORTALITY

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED MAY 9, 1901.

AUSTIN, H. W., surgeon. To proceed to Washington, D. C., for special temporary duty. May 9, 1901.

WOODWARD, R. M., surgeon. Granted leave of absence for ten days from May 7th. May 6, 1901.

STIMPSON, W. G., passed assistant surgeon. To proceed to Coalgate, I. T., for special temporary duty. May 9, 1901.

CLARK, TALIAFERRO, assistant surgeon. Granted thirty days' extension of leave of absence, on account of sickness, from April 21st. May 6, 1901.

ROBINSON, D. E., assistant surgeon. To proceed to Port Townsend (Washington) quarantine station, and report to the medical officer in command for special temporary duty. May 6, 1901.

MOORE, DUNLOP, assistant surgeon. That portion of Bureau order of April 18, 1901, directing Assistant Surgeon Moore to proceed to San Francisco, Cal., revoked. May 6, 1901.

RYDER, L. W., hospital steward. Granted leave of absence for fifteen days from May 6th. May 7, 1901.

FOR THE SEVEN DAYS ENDED MAY 16, 1901.

GODFREY, JOHN, surgeon. Upon being relieved by Surgeon J. J. Kinyoun, to proceed to Wilmington, N. C., and assume command of the service, relieving Surgeon T. B. Perry. May 11, 1901.

WASDIN, EUGENE, surgeon. To proceed to Gardner, Ill., for special temporary duty. May 14, 1901. Bureau order of May 14th, directing Surgeon Wasdin to proceed to Gardner, Ill., revoked. May 14, 1901.

PERRY, T. B., surgeon. Upon being relieved from duty at Wilmington, N. C., to proceed to Baltimore, Md., and report to medical officer in command for duty and assignment to quarters. May 11, 1901.

WOODWARD, R. M., surgeon. Granted ten days' extension of leave of absence. May 15, 1901.

YOUNG, G. B., passed assistant surgeon. Granted leave of absence for two months and twenty-two days from May 30th. May 9, 1901.

STIMPSON, W. G., passed assistant surgeon. To proceed to Guthrie, Oklahoma, for special temporary duty. May 14, 1901.

NYDEGGER, J. A., passed assistant surgeon. Granted leave of absence for one day. May 15, 1901.

GREENE, J. B., passed assistant surgeon. Granted leave of absence for ten days from May 15. May 14, 1901.

FOX, CARROLL, assistant surgeon. To proceed to Sitka and Juneau, Alaska, for special temporary duty. May 10, 1901.

THORNBURY, F. J., assistant surgeon. Relieved from duty at Chicago, Ill., and directed to proceed to Dutch Harbor, Alaska, and assume command of the service. May 16, 1901.

DUFFY, FRANCIS, acting assistant surgeon. Granted leave of absence for two days from May 21st. May 16, 1901.

ULRICH, C. F., acting assistant surgeon. Granted leave of absence for 12 days from May 14. May 10, 1901.

MASON, M. R., hospital steward. Relieved from duty at San Francisco, Cal., and directed to proceed to Dutch Harbor, Alaska, and report to medical officer in command for duty. May 16, 1901.

RECENT DEATH.

DR. JAMES HAYES, one of the oldest physicians in Central New Jersey, died at his residence in Plainfield on May 13th from cancer. He was graduated from Princeton in 1841 and from the College of Physicians and Surgeons, New York, in 1844.

Original Article.

THE DIAGNOSIS AND SURGICAL TREATMENT OF RENAL TUBERCULOSIS [1].

BY F. TILDEN BROWN, M.D., NEW YORK.

Your complimentary invitation to read a brief paper of this sort gave a double pleasure, in that it meant being present with you at so instructive a symposium and, again, because we inferred the possession of some items of interest which might be offered in partial exchange for the privilege. On reviewing our material, however, this was seen to be too scanty and intangible to shape up as a satisfactory contribution to the purely surgical treatment of renal tuberculosis, and we are therefore going to ask you to accept a recital of abbreviated histories given with the brief comments which seem best suited to bring out their salient features of symptom and treatment, whether this latter may redound to the credit of surgery, medicine, or neither.

For obvious reasons, in this malady, no one can speak authoritatively, either as to the final results of supposed radical surgical treatment, or, on the other hand, as to the certain progress towards a fatal termination of all cases which are not treated in some way.

Only a few cases fall to the lot of each observer, and even if we have been successful in overcoming the difficulties of determining the exact localization of the disease, the subsequent course of the patients and their residences are not easily kept track of. Some of the reported cures by nephrectomy are rather operative recoveries, and afford but temporary respite from the dangers of new foci of tuberculosis, because other lesser lesions had not been recognized, while not a few of the cases claimed as cures by climatic influence mean but a freshly fortified organism able to keep the disease in abeyance for an uncertain period. There is no fixed limit of time permitting the positive announcement of permanent recovery by either treatment. This is not meant to disparage the well-recognized value of both procedures; in fact, we would strongly advocate combination of the two whenever feasible; by which we mean that there are no cases of purely localized unilateral renal tuberculosis which we would entrust to climatic change as the best treatment, as opposed to surgery; and, on the other hand, there are no such cases just recovering from nephrectomy where we would not seek for the patient twelve months or more of this climatic benefit.

So, if we find here tonight two rival camps ready to contend for the custody of these sadly damaged pieces of humanity, the reader may not be found a very aggressive partisan of those who claim for surgery a radical cure in renal tuberculosis, except for the cases rarely seen and diagnosed early enough; namely, those where the disease is strictly limited to one kidney.

[1] Read before the Surgical Section of the Suffolk District Medical Society, March 6, 1901.

Despite the immense amount accomplished by earnest labor in the field of tuberculosis, we have yet to hope that something more specifically curative than the knife, sanitation or the piney woods may soon be hit upon.

In other localizations of the disease the importance of early diagnosis has long been appreciated. When the kidney is involved, recognition of the fact is apt to be unfortunately tardy. The trouble is not uncommon, consequently a diagnosis of pyelitis, nephritis or cystitis should not satisfy us until the etiology has been determined, or at least most diligently sought for. To secure more satisfactory results from surgical treatment, renal tuberculosis must be detected in anticipation of, rather than long after, the objective symptoms have become so conspicuous as not alone to render differentiation of the urines difficult, but to have involved so much of other parts of the urinary tract as to preclude a radical operation. Urinary analysis in general should mean as careful a routine search for tubercle baccili as is customarily given to the other formed elements of a sediment. When this is done, wholly symptomless cases of the disease will at times be discovered. Upon this initial evidence the suspicion should be verified and smegma bacillus excluded by getting the bladder urine through a catheter, then cystiscopic uretal catheterization may at once be utilized to locate the lesion in the bladder or kidneys. We believe there is no more accurate and simple way to do this in both sexes than with the writer's double-barrelled ureter cystiscope, each channel of which conveys a flexible sterile catheter to its respective ureter; by this means both kidneys are collected from at the same time, while the same nerve influences and the same physiological conditions pertain. With specimens thus synchronously collected, minor qualitative variations in the excretions of the two glands may be given a value they could not be allowed if gathered in the ordinary fashion, that is, one after the other. It is scarcely necessary to point out the service rendered by such a double ureter catheterization in giving information about the other kidney, even if the specimen drawn from the diseased organ fails to definitely determine the presence of tubercle baccilli.

We have seen more than a half dozen cases where an erroneous diagnosis of urinary tuberculosis has been made because smegma bacilli were repeatedly present in urine voluntarily passed; but none of the individuals were subjected to any operation or lost much time with needless treatment before the mistake was corrected by collecting the urine from the bladder by catheter and then demonstrating the absence of these bacilli. In one or two of the cases, where tubercle bacilli might have had an origin anterior to the bladder, animal inoculation of the normally voided urine was relied upon to determine the non-specificity of the bacilli found. We have seen no case where urines gathered from the bladder or kidney by catheter contained micro-organisms answering to tubercle bacilli and afterwards, by

operation or otherwise, found that any error had been made.

In connection with this subject it seems worth while to allude to an ambiguity seen in a recent small brochure, "Surgery of the Kidney," wherein the author [2] cites Mendelsohn's case of nephrectomy done for pyelonephritis, supposedly tuberculous, and where quite a misleading interpretation is given to the discussion which followed the operator's report. In this it is said, "Professor Leyden called attention to the great difficulty of making a positive diagnosis of renal tuberculosis by examining the excretions from the kidney and finding tubercle bacilli, on account of the almost omnipresence of the smegma bacillus in pyelitis and the great similarity of this organism to that of tuberculosis." A novice might too readily infer from the foregoing phraseology that the smegma bacillus had a habitat in the kidney when this was affected with a pyelitis. We have been unable to find recorded any case where this micro-organism has been proven to be anerobic.

Since there are cases of renal tuberculosis where the lesions are not in open communication with the urinary channels, hence the micro-organism not possibly attainable for microscopic or inoculation evidence, it is therefore proper that the symptoms, and any other aids in diagnosing the disease, should receive some brief attention.

It is not so very unusual for an open tuberculous renal lesion to shed so few bacilli that persistent microscopic search fails to find them. Here animal inoculation should always be early resorted to.

Sometimes the subjective symptoms are quite pronounced, even in the early stages of the disease; in other cases the pains are little noticed in advanced stages of the trouble, except by the behavior of the bladder, and too often these vesical symptoms are cited as evidence that this viscus is the original and only seat of the trouble. Coming to this point of our subject, it is clear that the topic cannot be handled without some reference to vesical tuberculosis, but this will be done only so far as it relates to symptoms or influences the treatment of the original invasion.

A dull aching in the lumbar region is significant; equally so is a much more acute kind of pain referable to the kidney or ureter. When these occur as crises, associated with nausea and vomiting, renal calculus or gravel colic is most apt to be thought of.

So many cases give a history of having had systemic manifestations resembling mild malaria, that we have come to look upon them as not infrequent precursors to the more distinctly localized later symptoms.

Commonly, however, patients will say they were never ill until their present trouble began with having to urinate too often, both day and night, and not infrequently they tell that they have had several recoveries from the annoyance, but each recurrence is more persistent than the last. We had once looked upon this thamuria as the classical and almost pathognomonic symptom of renal tuberculosis. Further observation tends to show that, in the majority of cases, frequency of urination appears not until the lower segment of the ureter has either acquired a genuine tuberculous lesion, or at any rate marked hyperemia and edema have developed, with an irritable state about the mouth of the ureter. We have in one case seen such hyperemic patches in a bladder which had to empty itself every hour or oftener. After the removal of a large tuberculous kidney, the ureter being left, the bladder recovered its normal repose. In this instance other micro-organisms in addition to tubercle bacilli may have come from the kidney and been responsible for these inflammatory vesical patches. That tubercle bacilli or their toxins can act as irritants and produce hyperemia and yet not affect an implantation at such points, we have some slight reasons to suspect.

The principal objective symptoms are a kidney which is larger and more tender than normal, as well as all grades of pyuria and hematuria, besides a just appreciable or a very marked diurnal variation in temperature; loss of color and weight; a reaction to tuberculin; finally, the presence of tubercle bacilli in the urine derived directly from one or both kidneys.

Since microscopic examination of the urine so gathered from a tuberculous kidney is not always affirmative, we think a great deal of value attaches to the injection of tuberculin. This would be used where a unilateral pyelonephritis was found in an individual giving some other suggestions of urinary tuberculosis, but at the same time running a nearly normal temperature. Should a fairly typical reaction here follow the injection, and could tuberculous foci in other parts of the body be excluded, we would feel pretty sure that guinea pigs inoculated by sedimental urine from this individual kidney would develop tuberculosis.

The test of such urines by sedimentation and growing of tubercle bacilli on culture media has not yet inspired general confidence. But we advocate the employment of tube cultures in all cases of ureter catheterization in order to determine the presence of other pathogenic micro-organisms, making the planting direct with five or six drops of urine as it falls from each ureter catheter. Although the majority of such tests have yielded us no growths, it is to be hoped that by persistent use data may be gradually accumulated which will add to the much yet to be learned regarding the reasons for the different clinical manifestations and apparent responses to various forms of medicinal treatment of renal affections. We have, for instance, grounds to believe that a renal tuberculosis, attended with some other form of infection, would act and react differently from a pure invasion of either single kind.

It is gratifying and surprising that so few deaths attend nephrectomy for tuberculosis. We have had to do with five, and seen perhaps twice as many done by others, where no fatalities occurred. Some

[2] Bayard Holmes, B.S., M.D.

of these cases, however, were very sick for several days, and with a full series no one could expect less than a 5% to 7% mortality. This, and the necessary uncertainty about the apparently healthy kidney, should make us investigate every case most thoroughly before proposing a nephrectomy. Then every precaution to have the patient in favorable condition is essential. In our limited experience persistent and exhausting vomiting has caused more solicitude than any threatening anuria. Consequently, the alimentary and urinary tracts, together with the kind and quantity of anesthesia, receive most attention. Three days may be taken for gentle but effective catharsis, and during the same time much larger quantities of fluid can advantageously be given. If the heart is unquestionably sound, chloroform is the anesthetic preferred; otherwise, nitrous oxide gas and ether.

The incision necessarily varies, being influenced by the proportions of the patient, as well as the size and position of the kidney. Whatever the line of approach, it is preferably extraperitoneal throughout. With a kidney nearly normal in size and position and a fair iliocostal space, the oblique lumbar incision answers every requirement for the kidney alone, or with not more than two or three inches of the attached ureter. To excise the ureter at the sacral brim, the lower end of this oblique incision must be carried well down and inward. A lateral posture of the patient is required for this lumbar incision. If the kidney alone is to be exposed or removed, an anterolateral incision approximating the costal curve can be done with the patient on the back. With a low kidney and lax abdominal walls, the patient being in the same dorsal position, a generous initial incision along the linea semilunaris can be used advantageously when the ureter also requires investigation or removal. On reaching the parietal peritoneum this is stripped away, while at the upper end of the incision another, more or less at right angles, is made outward. Then additional stripping of the peritoneum affords excellent access to kidney, and the ureter as low as the sacral brim. When the dorsal position can be employed, we believe it will be of advantage in guarding the other kidney from a degree of pressure possibly quite injurious in some cases.[2]

During a nephrectomy for renal tuberculosis, if the disease is seen to extend down the ureter to a point below the first sacral vertebra, we are not ready to urge that a total extirpation should then, or even at a later operation, be done. Several of our observations tend to the inference that a considerable amount of tuberculous ureter can be left with comparative safety; because, now being in a functionless state of repose, this particular focus is amenable to curative systemic processes. At the same time sufficient experience has not been accumulated to assert that a routine practice based on this presumption is always the best surgery. If total removal did not necessitate such an increased operative exposure, the radical step would better satisfy the surgical indications here just as well as in dealing with any tuberculosis.

If it were thoroughly ascertained that a ureter was diseased from kidney to bladder, and the operator felt inclined to do a total extirpation or none, it might improve the patient's chances to have a primary ureterectomy of the lower half, while the proximal end of the tube was given a temporary cutaneous implantation, there to drain the kidney until an early favorable time for nephrectomy. In this order the services of both kidneys would be available for convalescence from one operation.

Again, in some such cases, by passing before operation a ureter catheter carrying in its lumen a strand of chromic gut, this latter might be secured by needle to the severed ureter with the intention of invaginating the tube as it was stripped from the peritoneal attachment sufficiently low down to permit an inguinal or vaginal incision to extirpate the stump near the bladder.

We shall purposely omit reference to partial nephrectomy or nephrotomy and drainage in these cases, if for no other reason than that your time and the limits of this paper require brevity.

Even in cases presenting tuberculous vesical lesions where only one kidney is similarly diseased, we think that nephrectomy is indicated in a certain number of such individuals as offering the best chances for extension of life and comfort. Every reasonable effort should be made to determine the condition of each kidney before any operation is done for the relief of vesical symptoms, because nothing can be gained by this latter step so long as tuberculous debris is coming into it from above. Should efforts to ascertain the state of the kidneys be unavailing, then the epicystotomy done for drainage should be utilized to at once lead a small flexible ureter catheter into each ureter mouth, whatever treatment is immediately afterwards to be given the tuberculous bladder lesions. While it is not always easy to insert these ureter catheters even with the bladder opened above the pubis for visual inspection, still by having the proper catheters already led through the urethra, and one of them identified by an outside loop of white silk, then using a very short but large calibred cylindrical speculum which can act as a coffer or partial dam over much of the region surrounding one ureter opening, careful sponging will be apt to disclose the orifice. Now, seizing one of the catheters by a delicate spring forceps a half inch from its tip, it can be inserted and slowly advanced for the necessary two or three inches by successive short grasps of the forceps. It is highly essential to note whether it is the right or left ureter which receives the identified catheter. Artificial illumination, such as that given by an electric headlight, is almost indispensable for the accomplishment of this procedure.

If you can tolerate the review of several of the cases of renal tuberculosis with which we have

[2] Non-obstructive Post-operative Anuria, Annals of Surgery, March, 1901, p. 235.

had more or less to do, some items can be presented to show the basis for the rambling remarks just made. We trust these brief histories may make as good a framework for discussion of the topic as would accrue from a larger array of published generalized statistics.

We would take this opportunity to thank Dr. McCosh and Dr. Eliot for permission to include accounts of two of their patients; and at the same time to express our indebtedness to many others for interesting material we would otherwise never have had.

CASE I. An advanced case of right renal, vesical and prostatic tuberculosis, where climate and hygiene exerted a striking temporary benefit:

A. R., male, thirty-one years, Denmark. First seen April, 1892. One year before he had first noticed thamuria and occasional hematuria. He had been in various hospitals and repeatedly searched for stone. He is now urinating every few minutes during the day and involuntarily at night. Mingled with the urine sediment I found minute cheesy particles consisting wholly of countless tubercle bacilli. Reception for the patient was immediately sought of Doctor Trudeau, at Saranac, where, three months later, he had so much improved that he at times retained urine for two hours and gained strength and weight. Although during the fifteen months of residence in Saranac he was quite ill on three or four occasions, when new foci of the disease caused crises, he felt well enough at the end of this time to insist upon returning to New York to work. Almost at once the old urinary symptoms recurred, together with loss of appetite and appearance of large tuberculous lesions of the tongue. He died within two months.

CASE II. A quite chronic right renal tuberculosis coming to nephrectomy only after the kidney was immensely distended, and had by rupture initiated a perinephritic abscess simulating one of appendical origin. Excellent operative result. The left kidney had first given symptoms:

M. H., female, thirty, single, Ireland. First seen October, 1893. Has had slight cough for years. One year ago had a fall on the back; two weeks later pain in the *left* lumbar region, with nausea and frequent urination. On entering the Presbyterian Hospital, half hour urination, after which a reflex pain along the outer anterior surface of the left thigh. Urine contains pus and a few tubercle bacilli. Cystiscopy shows some discrete patches of hyperemia over the base. Rest and vesical irrigations during four months improved the condition, but menstruation was not re-established. For nearly two years the patient was not seen, when she summoned us in January, 1896, suffering with a large fluctuating tumor filling the entire right abdomen and pointing near the anterior superior spinous process. We sent her to the Presbyterian Hospital where, after evacuation of the perinephritic abscess, Doctor McCosh removed a very large pyonephritic kidney. Recovery uneventful but tedious. The frequency of urination was at once most favorably influenced by the nephrectomy, and when last seen, in 1899, she was passing urine only five times in twenty-four hours, and was again menstruating regularly. She had been for the past two years in quite good health and doing the services of a domestic. At this time of writing it has been impossible to get trace of the patient. Since the reading of this paper we have seen the patient; she is in even better health than when last reported.

CASE III. Showing the uncertainty of finding tubercle bacilli by microscopic examination, and where the evidence of animal inoculation would probably have saved much suffering and prolonged life:

A. D., female, sixteen years, United States. First seen July, 1893. Two years before, after fresh water bathing and a long cold drive immediately following, she had a chill, and shortly experienced left lumbar pain, then frequent urination and later suprapubic pain. At times all have been so severe as to be considered and treated as if of calculus origin. She brought analyses of urine by two different examiners, one reported the finding of tubercle bacilli, the other containing the diagnosis of renal calculus. We referred her to Doctor McCosh for operation. Numerous examinations by the pathologist of the hospital failed to detect tubercle bacilli in the urine. A nephrotomy was made evacuating a moderate amount of pus. Many mountings of this showed no tubercle bacilli. Had they done so a nephrectomy would have been done at once and thus pretty certainly saved the severe suffering constantly endured by the patient. Some months later, in another city, after nephrectomy, the patient died. The kidney was said to have been tuberculous.

CASE IV. Case lacking all the usual premonitory symptoms, although the kidney showed advanced caseous destruction of several pyramids and considerable pus foci. Most satisfactory result from nephrectomy. Now nearly seven years ago:

J. D., female, thirty-three years, married, Ireland. Seen July, 1894. No syphilitic history. Anchylosis of the right knee for nine years. She has never had any lumbar pain or noticed any urinary symptoms. She entered the Presbyterian Hospital in the service of Doctor Eliot for fracture of the right femur. After three weeks, while still abed, she developed a temperature the cause of which was not apparent; the patient felt well. Pus had suddenly appeared in the urine and examination discovered an enlarged right kidney. Tubercle bacilli were found in the urine. There were occasional chills. A week later nephrectomy gave a large tuberculous kidney. She was discharged with a small sinus in the loin which closed later. The patient has had one child since the operation, and is now in good health; she can eat and drink things which formerly caused her considerable distress.

CASE V.[4] Another chronic case showing absence of all subjective symptoms in a bilateral renal tuberculosis, and where an error would probably have attended the evidence given by ureter catheterization on the right side, had it been done. A good example of sudden acute miliary tuberculosis in a life-long scrofulous subject:

A. O., male, twenty-eight, Germany. First seen August, 1894. Always sickly as a child; knee joint involvement when twelve; recovery without anchylosis. Two years ago fell while carrying a load on the shoulder, weight striking him above the sacrum. Five weeks later an abscess pointed there, and knee joint again gave trouble, not improved by immobilization and iodoform injections. Three months later I resected the joint, and two months after a tuberculous testis was removed. Just before this latter operation I examined, by way of curiosity, the urine and found tubercle bacilli, although the urine was almost normally clear and there had never been any renal or urinary symptoms. During the next year we watched the patient with interest, always finding tubercle bacilli in the urine together with a very few leucocytes. No symptoms could be elicited to suggest their place of origin and the man was gaining strength and weight

[4] Illustration of entire urinary tract, Presbyterian Hospital Report, 1899, p. 61; also New York Medical Journal, 1896.

but losing color. Four months later he was brought to the medical service of the hospital with a brief history of a rather sudden onset two weeks before of what had been diagnosed typhoid fever. On admission examination suggested acute miliary tuberculosis, but sputum showed no tubercle bacilli. Death three days later. Autopsy showed acute miliary tuberculosis of both lungs. The urinary organs disclosed two tuberculous dilatations near the middle of the left ureter and two rather small necrotic foci in each kidney. Those in the left were in open communication with the urinary channel, while those in the right were apparently not so, and, had urine been gathered by ureter catheter from this side, probably neither tubercle bacilli or leucocytes would have been found in it.

CASE VI. Case of emergency nephrectomy yielding, as expected, a tuberculous kidney. Remarkable systemic improvement as well as relief of urinary symptoms were followed five months later by a new focus of the disease and death:

W. C., male, fourteen years, United States. First seen August, 1896. One year before had fallen from a tree; three months later frequent and painful urination. Six months later another surgeon found good reason to make a suprapubic cystotomy, and removed a very large soft mortar-like calculus. At the same time he discovered a tumor in the right loin. This increased rapidly and one month later the patient was sent to me for immediate nephrectomy at the Presbyterian Hospital. The boy was much emaciated and had an immense tumor of the right kidney. The urethra was occluded and all urine passed through the suprapubic fistula. The history and present condition suggested to us that the kidney was tuberculous and had been the original seat of all his urinary disease. A kidney greatly enlarged by many pus foci was removed extraperitoneally. The greater part of a large indurated ureter was not removed. Three weeks later internal and external urethrotomy for the tuberculous obstruction of the urethra with curettage of the suprapubic sinus. Six weeks later both sinuses closed and all urine passed by the urethra. Left hospital with a gain of 30 pounds. He was feeling comparatively well when five months later I saw him with tuberculous meningitis. Death in ten days. At autopsy we noted a striking diminution in the size of the right ureter. When this case was reported[5] it was said that, in view of the non-hygienic conditions of his home, some early relapse was to be anticipated.

CASE VII. A case of bladder tuberculosis, with doubtful involvement of the left kidney, but reported to illustrate the benefit which may result apparently from a strictly hygienic life and local treatment:

C. K., male, forty-four years, United States. Seen May, 1895. No venereal disease. Father and his six brothers and sisters all died of consumption between the ages of twenty-five and forty. Both of his father's parents were consumptive. The patient, a man of fine physique, weighing 185 pounds, had believed himself to be perfectly well, except that five years ago an attack of malaria had kept him from business five or six weeks; possibly had some minor bladder symptoms a short time after, but these yielded to treatment. About January, 1893, he first noticed a drop or two of blood at the end of micturition and a slight tingling in the glans penis. Thinks he had a slight similar manifestation two years before which yielded to beechwood creosote. Frequency now amounts to every two hours; if held longer there is apt to be a little more blood. Prostate and vesicles, as well as external genitals, normal. Palpation of the left kidney causes slight pain. Urine quite muddy, with pus. Specific gravity 1.015 (and it has never been found higher). Marked trace of albumin. First examination for tubercle bacilli revealed eight or ten; never found subsequently. The afternoon temperature was 100°. Cystiscopy reveals a congested trigonum, and about the left ureter a lesion about an inch in diameter, nearly half of it an open ulcer. The patient was advised to seek an open air life in the Adirondacks. For two years he lived in the mountainous parts of New York or North Carolina with decided benefit. During this time his urinary intervals increased and blood was noted only a few times. The exigencies of life then compelled him to accept a non-confining business in New York. His attention to every hygienic detail of life was the most perfect. After his return some of the old symptoms began to trouble him, and he again sought treatment. Tubercle bacilli could not be found by microscope, and some doubts were hoped for regarding our diagnosis, but guinea pig inoculation was confirmative. At the expiration of a year or more, the slight bleeding was commonly manifest and irritability of the bladder more and more bothersome, but never of the extreme type. The old ulcer at the mouth of the left ureter was still to be seen, but smaller.

He insisted that it was impossible to give up business again and that something must be done medically or surgically for his relief. I could think of nothing more promising than a suprapubic cystotomy to permit curettage and cauterization of the single bladder ulcer and at the same time catheterizing the ureter of the questionable left kidney. Not only was this not urged, but it was most reluctantly submitted to the patient in answer to his demands for treatment. Fortunately, I believe, for us both, he was advised by friends to seek some other alternative. Going to an esteemed confrère, with my introduction, he was urged to leave New York again. When this was explained to be impossible, vesical irrigations were employed by his new physician with pretty prompt beneficial results. For the past two and a half years he has continued treatment, going into camp life during summer vacation. I have had occasional opportunities to inquire of the patient, and only a few days ago he told me that urine is now retained for from five to seven hours, and that he is practically unaware of any urinary disturbance.

CASE VIII. A case of urinary tuberculosis. Strong suspicion of a right renal origin, but proof by microscopic examination of right ureter catheter specimen was not affirmative. Animal inoculation tests should also have been made. The patient writes from Italy that he is about as well as when first seen:

A. D., male, thirty-five, Italy. Seen July, 1898. Six months before urination became frequent; pus and occasional blood noted; pretty constant pain above the symphysis. Tubercle bacilli were found at times in the voluntary urine. I catheterized both ureters twice because a marked pyelonephritis was found in the right side, but the microscope discovered no tubercle bacilli either time. Urine from the left kidney was normal. The cystiscope showed a very hyperemic and gaping condition of the right ureter mouth. Patient's vesical symptoms considerably improved during five months' hospital rest, hygiene and boric acid irrigations, and he returned to Italy.

We believe the kidney to have been tuberculous and think it unfortunate for patient, despite his present report, that tubercle bacilli were not detected in the right kidney urine so as to have justified a nephrectomy.

CASE IX. Illustrating rather unusual periodicity of symptoms in a case of pretty certain left renal tuberculosis. Microscopic examination of a single ureter catheter specimen unsatisfactory. Great fluctuations both in the condition of the patient and her left kidney during two years and a half. Present state as inferred by letter one of

[5] Medical and Surgical Report of the Presbyterian Hospital, 1897, p. 49. Renal Tuberculosis, p. 49; also New York Medical Journal.

considerable improvement over that of a year ago:

J. G., female, twenty-two, United States. Seen but once, May, 1898, when referred by Dr. Trudeau for ureter catheterization. She had had pulmonary trouble for some time. Two years ago she first felt pain along the crest of the left ilium, radiating to groin, with nausea. At that time pain disappeared on reclining. Three months ago, while at Saranac, had persistent left lumbar pain for six weeks, nausea and often vomiting. Pain had a regular afternoon exacerbation lasting five or six hours. Lost about 15 pounds. Had a slight thamuria. At the time the patient was examined when passing through New York, I did not know that Dr. Trudeau had found a few probable tubercle bacilli in the urine, and that affirmative evidence was about to follow his animal inoculations. Had this been known, the same test would have been used with the urine gathered from the left kidney. Our microscopic examination of this urine showed a pyelonephritis, but tubercle bacilli were not found.

A recent letter from the patient's mother tells that two months after this examination there was great increase in the size of the left kidney and great suffering. After another two months this was gradually recovered from. For the next two years the benefits of various climates were sought, and although different joint, skin and pulmonary complications appeared, the patient gradually got better of each, and now, with the old cough persisting, the kidney shows scarcely any enlargement and no pain, the urinary system giving scarcely any annoyance. Careful microscopic examination of urine just sent me shows no tubercle bacilli.

There is room for speculation as to whether the patient would be in better or worse condition today had nephrectomy been done three years ago. Possibly the kidney is now destroyed and its ureter occluded.[6]

CASE X. A second case of renal tuberculosis, with no vesical symptoms. Also a good example of promising radical cure by an early diagnosis and early nephrectomy:

P. A., female, thirty-four years, Germany. Seen October, 1898. Rather marked family history of tuberculosis. Well until four years ago; then a nondescript illness was improved by a trip to Europe. Two years ago first noticed occasional dull aching in the left lumbar region, gradually increasing in severity. Three months ago had severe pain with nausea and vomiting lasting three hours. Has frequently had similar half-hour recurrences since then. Pain always begins at a definite point over the left ureter on a line with the umbilicus; then radiates to kidney and back. The periods and comfort of urination not affected nor have they ever been. Has lost 20 pounds in three months. Palpation over the left kidney causes some pain. My first examination of voluntary urine showed tubercle bacilli. Cystiscopic ureter catheterization revealed no vesical lesion, and gave a normal urine for the right side, while that from the left showed a pyelonephritis and tubercle bacilli. Patient readily accepted the proposition of nephrectomy; done under chloroform, November 26, 1898. Six inches of ureter removed with the kidney.[7] The latter had but a single focus of disease at the apex of one pyramid, a few tubercles in the pelvic, while the ureter just above and for three inches below its renal attachment was greatly thickened in the submucosa, so as to favor temporary occlusion. This would appear to explain the nature of the pains experienced. After operation the patient had the advantage of six months' care under Dr. Trudeau at Saranac. She is now very active and claims to be in as good health as she has ever known. This is the only case of renal tuberculosis we have had where cystiscopy showed no vesical lesions, even a trifling hyperemia about the ureter opening.

[6] Illustration of such condition. Presbyterian Hospital Reports, 1897, p. 45.

[7] Illustration, Annals of Surgery, March, 1901, p. 229.

CASE XI. A case of pretty advanced renal tuberculosis and apparent cure by nephrectomy, although the vesical symptom of frequency still persists.

A. W., female, thirty-four years, United States. Seen October, 1898. Strong family history of tuberculosis. When twenty-three years old patient gave manifestations of a general decline; moved to the country to live and improved. Three years ago she had occasional pains in the right lumbar region and first noted frequency of urination. In 1897 the thamuria was every fifteen minutes. In September, 1898, she had chills and fever. Dr. E. E. Smith, of New York, found malarial organisms in her blood and, being struck with the urinary symptoms, examined for and found tubercle bacilli in the urine. He then referred her to us for localization of the disease and treatment. Cystiscopic ureter catheterization showed a greatly congested trigonum and a gaping edematous right ureter. Urine from the right side evidenced a marked pyelonephritis with tubercle bacilli, that for the left ureter a normal kidney. Lumbar pain and general unrest were so distressing that she eagerly accepted nephrectomy. This was done on December 7, 1898, under ether anesthesia. Nearly eight inches of the ureter was removed with the kidney.[8] The latter showed four of its pyramids nearly destroyed, while the ureter was much dilated but soft and studded with tubercles. These evidently were continuous in the part not removed. The patient made a slow but good recovery. Now she has no pain. She has gained 75 pounds and does all her own household work. The remaining diseased ureter or a bladder much contracted before the operation may be responsible for the still persisting painless thamuria. Whatever its cause, frequent microscopic examination of the urine since nephrectomy has failed to discover tubercle bacilli. Animal inoculation will shortly be made when the patient returns to New York for vesical irrigations, which she has thus far not seen fit to bother with since she and her family view the case already as a cure. Since the reading of this paper the patient's urine has responded negatively to animal inoculation, and bladder washings have greatly benefited the frequency.

CASE XII. Case of right renal tuberculosis; the strong suspicion that the left was also tuberculous appeared to warrant nephrotomy only.

D. P., male, thirty-five years, United States. Seen March, 1899. Ten years before severe laryngitis, ascribed by some consultants to tuberculosis, by others to syphilis which he had had. Six months ago he first felt occasional pain in each lumbar region, and shortly after he experienced frequent and somewhat painful urination. He has had the benefit of various climatic changes. Has lost much during past half year. He is now urinating every hour and a half. Marked pyuria and tubercle bacilli present. Palpation of right kidney painful, not so over the left. Cystiscopic ureter catheterization shows some small open ulcers about the right ureter and edematous state of its opening. General hyperemia of the entire base. A pea-sized tumor just in front of the left ureter makes it impossible to pass a catheter. The urine drawn from the right ureter evidenced a pyo-neprosis with tubercle bacilli. Patient desired nephrectomy, but his unfavorable condition and appearance of general dissemination of the disease led me to offer nephrotomy, by which considerable pus and necrotic material was evacuated. This permanent drainage was maintained with some relief of the urinary symptoms until death by exhaustion nine months later.

In this case left kidney urine was collected from the bladder while the right ureter was plugged and being drained by a catheter. In one such collection tubercle bacilli were found; at the second trial they were not. Such a test of the kidney's condition, where the bladder is diseased, is not reliable.

[8] Illustration, Annals of Surgery, March, 1901, p. 227.

Case XIII. A case of right renal tuberculosis where nephrectomy was declined, and the patient now claims she is getting well:

C. B., female, thirty-one, United States. Seen July, 1899. For past two years she has had occasional sharp pain in the right lumbar region. Six months after its appearance she noticed frequent urination and sometimes bloody urine. The right kidney is found to be hard and enlarged. It is tender and nearly all below the costal margin. Tubercle bacilli have at times been found in the voluntary urine. Cystoscopic ureter catheterization shows no general vesical lesions, but the mouth of the right ureter is swollen and hyperemic. Contraction of the muscular coats of this ureter upon the catheter are evidently painful, for with each intermitting discharge of several urine drops the patient complains. Urine from the right kidney shows a pyelonephritis and tubercle bacilli, that from the left kidney is normal. Judging from behavior and expression this patient had much lumbar pain, and the case seemed unusually favorable for a nephrectomy; when proposed however, she left the hospital. Efforts to learn her present condition brought a letter from her "clairvoyant physician" and one from the patient. That from the latter is the more explicit, and in part is as follows: "I have been doctoring on and off since I left the hospital, with different ones, and at last I think I have struck the one that is going to cure. . . . I have been gaining slowly ever since I left the hospital, and feel very thankful I did not stay for the operation you were going to put me through. . . . My health is better in every respect, and I hope in short to be a well woman. I have been under entirely too many operations for my own good already."

Case XIV. Case showing chronicity and good behavior of a tuberculous kidney without treatment:

M. I., female, sixty-two years, United States. Seen May, 1899. Father and nearly every one of his immediate relatives died of consumption. The patient has always been delicate and nervous. Has had many serious illnesses. Four months ago, when lifting, felt a pain in the left lumbar and inguinal region radiating to the perineum. Hourly urination with burning, moderate afternoon rise of temperature. Urine contains considerable pus, marked trace of albumin and many tubercle bacilli. Left kidney is tender and palpable. Cystiscopy shows no open bladder lesions but a congestion and edema about the left ureter. While in the hospital the vesical symptoms were considerably improved, apparently by boric acid irrigation. Then she declined further observation or treatment. Now, after much search, we find her in an old ladies' home looking better than two years ago, and claiming that her side is not so painful, nor her urination so frequent as when in the hospital, but she will permit no examination.

Case XV. A second case of apparent cure of renal tuberculosis by nephrectomy, but with persistence of frequent urination:

I. C., male, thirty-two, Hebrew. Seen August, 1899. Tuberculosis on the mother's side. The patient has had a slight cough as long as he can remember, but has always been unusually strong and vigorous. Seven months ago he first felt dull pain in the right loin and noticed frequency of urination. He entered a hospital where he had at times high temperature. He left suddenly, frightened at a proposed cystiscopy. His lumbar suffering has steadily increased; now urinating every fifteen minutes. Neither kidney palpable, but firm pressure over the right causes some pain. Our first examination of urine shows tubercle bacilli. Cystiscopic ureter catheterization reveals a congested trigonum with more marked hyperemia and edema of the right ureter. Right kidney urine evidences a pyelonephritis and tubercle bacilli. Urine from the left kidney is normal. He desires immediate removal of the diseased organ. This was done under chloroform, August 29, 1899. The kidney[9] was large, the cortical surface and pelvis were studded with large tubercles; it is presumed that the ureter was also implicated, but for reasons it was not deemed advisable to explore or try to remove any of it. The patient's abdomen was large, its muscles were in a state of tonus during the operation, and an old appendicitis cicatrix, which was almost a hernia, was to be avoided. The patient made a good recovery. At times, while in the hospital, he had three-hour urinary intervals, but now he says they are as often as every twenty or thirty minutes. Many subsequent and some very recent microscopic examinations have failed to detect tubercle bacilli in the urine. The former pain is gone and he works hard as a peddler.

Here, as is suspected in the patient A. W., Case XI, the presence of a diseased ureter may be the cause of the thamuria. But in this patient's case, also, there has never been any intravesical treatment since the operation.

Case XVI. Illustrating the occasional difficulties of proving a tuberculous kidney to be such. This case might have responded negatively to the animal inoculation test, probably affirmatively to tuberculin:

P. M., male, forty years, Italy. Seen November, 1899, to examine bladder and collect urine, at request of Dr. Bolton. Patient had had malaria in 1884, otherwise healthy until April, 1898, when micturition was as frequent as thirty or more times a day and continued so for two weeks, then improved materially. Four months ago pain was first felt in left lumbar region, continuous and does not radiate. Little or no pain now during urination, but this is frequent. Left kidney is palpable and tender.

Cystiscopic ureter catheterization shows hyperemia and swelling about the left ureter. Urine from the left kidney shows a marked pyelonephritis, but no tubercle bacilli. Urine from the right kidney normal. The voluntary bladder urine also failed to reveal tubercle bacilli. In this case Dr. Bolton made a successful nephrectomy. From his report[10] it is only necessary here to quote the following: "The kidney was considerably enlarged . . . presenting several rounded eminences . . . filled with semifluid pus and caseous material. On section this lower half of the kidney is converted into three distinct and several smaller cavities, one of which is larger than the others, is empty and communicates with the pelvis. The walls of all these cavities are very actively inflamed . . . and on microscopic examination show numerous miliary tubercles . . . smears of the contents of these cavities show neither tubercle bacilli nor other bacteria after a lengthy search. In the sections, however, tubercle bacilli were demonstrated in the miliary tubercles."

Case XVII. In this case there was a probable mistake in not making a cystiscopic ureter catheterization and urging an immediate nephrectomy if tubercle bacilli had been found in urine of the suspected kidney. The case also illustrates temporary climatic benefit, and the fallacy of bladder drainage when either kidney is the seat of tuberculosis:

F. M., male, twenty-nine years, United States, fireman. Seen May, 1900. The patient has always been well and strong, but at times during the past two years he has had mild attacks suggesting malaria. Five months ago, during the winter months, his duty as fireman obliged him on three occasions to stand for an hour or more in the cellars of burning buildings when the water was above his waist. Two weeks after the

[9] Illustration, Annals of Surgery, March, 1901, pp. 231 and 233.
[10] Annals of Surgery, June, 1900, p. 749.

last such exposure he experienced a pain in the right lumbar region, together with bloody and frequent urination. Now, on entering the hospital, he urinates every half hour and has a slight afternoon rise of temperature. Characteristic reaction to two milligrammes of tuberculin and tubercle bacilli found in the urine. He has had, elsewhere, a great deal of bladder sounding for stone, so we make no instrumental examination, but advise an immediate change of air and to report on his return. We have not seen him since, but learned the following from his wife. He went to the Loomis Sanitarium, Liberty, N. Y., for two months, where he gained 14 pounds, besides being able to take long walks without pain and hold his urine for four hours. He then felt well enough to take up work again. Two days after reaching New York the hematuria and frequency recurred, and, continuing to get worse, he one month later entered the Homeopathic Hospital where a suprapubic cystotomy was done for permanent drainage. He has never left his bed during these five months, and his death is daily expected.

CASE XVIII. A case of right renal tuberculosis, where postponing nephrectomy may have been a mistake:

E. N., female, twenty-two years, United States. Seen August, 1900. One and a half years ago, and six months after the birth of her child, she first experienced frequent and somewhat painful micturition lasting only three weeks. Some two months later the annoyance recurred, to be again recovered from. But for the past seven months these symptoms have been continuous and are intensified just before menstruation. Has had no pain in either lumbar region, but the right kidney is distinctly palpable and tender. Cystiscopic ureter catheterization shows only some hyperemia and edema about the right ureter. Urine from the right kidney evidences a moderate pyelonephritis and contains tubercle bacilli. Left kidney urine normal. As it was the middle of a hot summer, when the patient would evidently derive great benefit from country air and be in better condition for operation, I sent her to the mountains for two months, to report on return. A letter written two weeks after she had reached the Catskills told of improvement. She has not been seen since. To properly complete this history persistent search has been made for the patient, but resulted only in an indirect report that she is now very ill, her whereabouts being withheld.

A retrospect of our own limited material leads to the conclusion that too great pains cannot be taken by physician and surgeon to determine the location and extent of the disease before determining upon the treatment. The integrity of the other kidney, of course, has great bearing on the surgical aspects of any case. To determine in any particular case just what rate of progress the disease may pursue if left untreated, or what degree of immunity from some of the annoying symptoms we can promise the patient by a nephrectomy, is not easy.

In ward hospital cases the immediate operation appears to be the only alternative. For those who can afford climatic changes and rest a careful preliminary observation of the existing conditions of the urinary tracts should precede their travels, and the same examination, when at all indicated, should be repeated in order to keep posted regarding such an advance of the disease as to call for operation.

L. Emmett Holt has been chosen clinical professor of diseases of children at Columbia University.

Clinical Department.

ASTHMA.[1]

BY F. P. EMERSON, M D., BOSTON.

IF we turn to general treatises on internal medicine, we find the pathology of asthma very indefinite. In fact, there is a description of the symptomatology, and not of a pathological process at all. At one time it is stated that there is a hyperemia of the bronchial mucous membrane, with a characteristic exudate of mucin due to pneumogastric or vasomotor functional disturbances. At another that there is no lesion whatever, and the condition is a pure neurosis, the exciting cause being anywhere in the body, with morbid changes found at autopsy due to the resulting chronic bronchitis pulmonary emphysema and right ventricular hypertrophy with dilitation. If we turn to special investigators, there is not here that unanimity of opinion we would expect. Some authorities considering it a vasomotor bronchitis analagous to the rhinitis of hay fever, and that both are a neurosis, which in their chronic form become a neurotic habit due to an unstable condition of the nervous system. Others attribute importance to a psychic influence with only occasionally a local disorder. While others assert that the condition is due to the individual as a whole and not to any particular peripheral irritation or to varying ones. A few favor the auto-toxemic theory, while an increasing number claim that the whole question turns on the integrity of the respiratory function of the nose, and that the essential condition is an ethmoiditis amenable to treatment.

The following cases are offered as simply showing the trend of my observations, and not the final word in this disorder:

CASE I. Spur opposite Middle Turbinate.

CASE I. Miss R., single, thirty years. Born in Woburn. Seen November 20, 1896.

Family history.— Negative except father's cousin, who died of asthma.

Past history.— Had pleurisy and pneumonia seven years ago. Sick five weeks. Asthma commenced two years ago, the attacks increasing in frequency and duration. Menses regular. Some cough all the time, but only a little between the paroxysms. Signs of bronchitis general, but more

[1] Read before the Clinical Club, March 11th, and the Roxbury Clinical Record Club, February 5, 1901.

marked over the left lung, and quite free at the apex of the right. Heart action negative. Bowels regular. Has lost fifteen to twenty pounds of flesh and is cyanotic, with the stooping shoulders of a confirmed asthmatic. Changed residence, as the parents thought she had phthisis.

Present illness.— First seen November 20th in an acute attack, and by December 17th she had so far recovered that she went in town; took cold and had a relapse. This history repeated itself, so that it was in the early spring before she was in condition to undergo any radical local treatment. At this time examination revealed a spur in the right naris opposite the middle turbinate, and well back on the vomer, which was removed. The attending subacute rhinitis and ethmoiditis received appropriate treatment, and she rapidly gained flesh and strength, and has since worked in her father's bakeshop without any relapse, which now covers a period of five years.

Case II. Ridge running through the Inferior Meatus.

Case II. Mrs. H., age twenty-eight years, was referred to me by Dr. C., January 23, 1900. Is now being treated for nervous exhaustion, and comes to me on account of sneezing hydrorrhea; asthmatic breathing and cough, particularly on rising, which had followed a cold the October previous.

Family history.— Negative.

Present history.— Married four years. Three years ago overworked; one miscarriage followed by some local operation. Good recovery. Menses regular but scanty. Has frontal headache and backache. Pupils dilated. Asthma constant in the morning.

Examination.— Temperature and pulse normal. Chest negative; cough constant. Acute rhinitis. Left naris encroached upon by a ridge opposite the inferior turbinate. No separation of cartilage. No myxomatous tissue. Second turbinate normal. On right side ethmoid cells covered by acute secretion, with anterior and posterior discharge.

Treatment.— No internal remedies given, but cough diminished and all symptoms subsided with the cure of the ethmoiditis. She has now been free from asthma one year, although her general health remains poor.

Case III. Mrs. P., 75 years. Born in Yarmouth, N. S. Six children well.

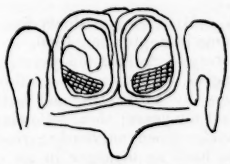
Family history.— Father died at eighty years; always well. Mother died at ninety years; always had asthma, as did her five sisters. One brother died of apoplexy; two sisters of phthisis; one sister of apoplexy, and was always an epileptic.

Past history.— Had croup as a child, beginning at one week. At seven years had asthma badly until she was ten, and has been entirely free until two years ago, when, at seventy-three, she had a nasopharyngitis followed by pneumonia, and has had asthma continuously since with the exception of two days while away in the summer. Since the nasopharyngitis there has been continuous dropping from her head, and a sensation of stuffiness on the right side which she had not had before.

Present history.— Was wiry and active and remarkably well until two years ago. Heart, lungs, kidneys and bowels normal. Stomach occasionally becomes disordered, usually from constipation. Some arteriosclerosis but not marked. Commenced local treatment January, 1901.

Examination.— Nares narrow and a little more free on the left side. Mucous membrane thin

Case III. (*a*).— Adhesion between Middle Turbinate and Septum; both Middle Turbinates cystic anteriorly.



Case III. (*b*).— Middle Turbinates hypertrophied posteriorly.

and not injected. Inferior turbinate not enlarged, and normal space between it and the septum. Middle turbinate anterior ends both cystic, and on the right side there is an adhesion to the septum, with cell proliferation opposite the second turbinate. The nares being narrow, the whole space between the septum and the nasal wall is filled, and on the right side there is marked obstruction to drainage from the ethmoid cells. No myxomatous degeneration. There is free dropping into the pharynx, and a sensation of stuffiness on the right side. During asthmatic attacks this side is blocked up, and on the inhalation of volatile remedies much mucous is released, and the attacks are always relieved temporarily. Syringing brings away characteristic flocculent mucous from the ethmoid cells. Asthmatic attacks start with a nasopharyngitis followed by

bronchitis, and at one time with pneumonia. Septum normal and also the columnar cartilages, with no thickening of the vomer posteriorly. Larynx normal and urine negative.

Treatment.— The adhesion between the septum and turbinate was relieved and the ethmoiditis cured. Local treatment, which was commenced January 1st, stopped all dropping posteriorly, and in two weeks the asthma ceased, being the first cessation, since it began two years ago, except for two days. This immunity still continues April 1st, at date of writing.

CASE IV. (*a*).— Second Turbinate Myxomatous; Septum deflected, involving Triangular Cartilage and Vomer.

CASE IV. (*b*).— Posterior extremity of Inferior Turbinate presents Cauliflower Hypertrophy.

CASE IV. Miss C., age thirty-five years, was referred to me in September, 1900.

Past history.— Asthma ten years. History of nasopharyngitis, which would be followed in four or five days by bronchitis and asthma. Had taught school ten years; then, following an attack of grip, broke down nervously; recovered and now works hard as manager in an office down town.

Family history.— Negative.

Examination.— Columnar cartilage dislocated into left naris. Triangular cartilage deflected to the left, involving the vomer, with marked cell proliferation opposite the second turbinate. Inferior turbinate hypertrophic, and middle turbinate anteriorly seat of myxomatous degeneration, especially on the left side; ethmoiditis; posterior hypertrophy of both inferior turbinates, with cauliflower appearance, and also posterior hpyertrophy of second turbinate. Tonsils fibrinous; chronic catarrhal process in both ears, with diminished hearing and feeling of obstruction in right ear from closure of the Eustachian tube. Heart and lungs apparently normal, except for the bronchitis.

Treatment.— The columnar cartilage was removed on the left side, and also the myxomatous tissue and both posterior hypertrophies. Ethmoid cells were cleared out and the tonsils opened up. Tonics and diet. For fifteen months previous to treatment she was never entirely free from a sense of weight and tightness across the chest, and during most of this time averaged to be up at night two out of three nights, generally from 3 to 5 A.M. Commenced treatment the middle of September, and was up as usual through November, but since then she has not been disturbed except two or three nights following a cold. For the last two months she has felt no chest discomfort or pressure, and there is very little post-nasal discharge and no asthma.

CASE V. Septum deflected to the right; horizontal Ridge through Inferior Meatus.

CASE V. Mrs. S. was referred to me August 8, 1900, by Dr. A., with the following history: Dr. A. was called at 11 P.M. and found the patient with an acute nasopharyngitis following exposure after being overheated. She awoke in the night with a smothered feeling accompanied by cough and wheezy respiration. Relieved by poultices and morphia. History of a previous attack the August preceding, which lasted six months, accompanied by sneezing, with pain and discomfort over the bridge of the nose.

Past history.— Mrs. S. was born in Scotland, and as a girl had repeated head colds. Three years ago she moved to Vermont, where she was apparently well. She came to Boston in April and in August she had the attack as given above, which lasted six months, and then came on the succeeding August, when seen by Dr. A.

Family history.— Negative. She is robust, with two healthy children. No asthma in the family.

Examination.— The septum is deflected to the right, including all the triangulur cartilage, and through its lower part is a horizontal ridge extending back through the inferior meatus and touching the inferior turbinate, so that the right side is practically occluded and covered with acute secretion. There is moderate posterior hypertrophy of the inferior turbinate. There is an anterior and posterior ethmoiditis in the acute stage.

Treatment.— The ridge was removed and the ethmoiditis cured. April 1st, she remains well, and has had no cold or asthma during the winter.

GENERAL SUMMARY.

The foregoing cases are not sufficient in number, nor have they been under observation for a

period warranting any definite conclusions; but they are offered because here in every case is a definite pathological condition found in the respiratory tract, where we would logically expect it as a sequel to the nasopharyngitis, a clear history of which was obtained either as an acute or subacute inflammation in every case. While the gross abnormalities of the nose were corrected, and the general condition improved as far as possible, this had no apparent effect on the asthmatic attacks, which, however, yielded readily to local treatment, with freedom from recurrence in proportion as we were able to control or cure the ethmoiditis.

A CASE OF TRICHINOSIS.

BY GEORGE G. SEARS, M.D., BOSTON.

M. D., an Italian laborer about twenty-four years old, was admitted to my wards in the City Hospital, December 6, 1900. Six days before entrance he was attacked with pains in the legs and arms and a slight diarrhea, which was soon followed by constipation. He felt feverish and chilly. Soon after the appearance of the first symptoms he noticed considerable swelling of his face. He was a well-developed and nourished man, whose puffy face and eyelids, combined with his pallor, suggested an acute nephritis. The skin was hot and dry. The forearms and legs were swollen, the result rather of a general increase in the size of the muscles than of any change in the skin, which was not edematous. There was tenderness along the outer sides of both tibiæ, as well as in the muscles of the calves, thighs and forearms, though in the latter situation it was less marked. The heart was laterally enlarged, and later a soft systolic murmur developed over the pulmonary area. The liver and spleen were normal. The tongue was heavily coated. A blood count showed 16,200 leucocytes, of which 17½% were eosinophiles. Two days later the white cells numbered 9,500, 13% being eosinophiles. The reds numbered 5,240,000, and contained 90% of hemoglobin. The urine was concentrated, but was not otherwise noteworthy.

December 10th. A well-marked urticarial eruption appeared over the trunk and thighs. The face is less puffy and the muscles less tender.

December 17th. The temperature, which reached 104° as its highest point and closely simulated typhoid fever in its course, returned to normal by lysis two days ago. Swelling and tenderness of the muscles had gone. The cardiac area was enlarged and extended three fingers' breadth beyond the right sternal border, and on the left one-quarter inch beyond the mamillary line. No murmur was heard. The liver reached from the fifth space to an inch below the costal margin, but the spleen could not be felt. The white cells numbered 10,800, and contained 31% eosinophiles.

White counts made on December 19th and 23d, and on January 3, 1901, showed, respectively, 9,800, with 39% of the eosinophiles; 12,400, with 33%, and in the last count 23% of the eosinophiles.

He improved steadily and was discharged January 3d. His muscles were still weak and flabby, but the heart had returned practically to within normal limits. A piece of the left gastrocnemius was removed on December 8th and submitted to Dr. Mallory, who reported acute myositis with occasional degeneration of muscle fibres with infiltration with leucocytes. No trichinæ. Ten days later a larger piece was removed from the right gastrocnemius, in which trichinæ were so abundant that thirteen were seen in one microscopic field.

The preceding case is the twenty-fifth which has found its way into literature since the discovery at the Johns Hopkins Hospital of a marked eosinophilia in trichinosis. All have been reported by American observers, and all have confirmed the first observation, with the exception of a fatal case reported by Howard, in which no differential count was made ante-mortem. An increase in the number of eosinophilic cells has been found as early as the fifth day, the earliest date on which a count was made, and in a case reported by Stump they still composed 15% of the whole at the end of four months. The proportion has at times reached extraordinary heights, 60% being exceeded in several instances, while in a case reported by Kerr it was over 80%. It is noteworthy that the higher counts were made comparatively late in the disease, days or even several weeks after the initial symptoms, and even after the fever had gone down and general improvement had taken place in the patient, so that, while the migrations of successive crops produced by the parent worm in the intestine might account for the earlier variations, they do not seem to explain the large numbers which appear so late that reparative processes must have already begun. The severity of the disease seems to have no effect on the relative number of these cells, but it may influence the extent of the leucocytosis.

Medical Progress.

RECENT PROGRESS IN OTOLOGY.

BY PHILIP HAMMOND, M.D., BOSTON.

ANATOMY AND PHYSIOLOGY.

Zimmerman[1] advances the theory that sound vibrations are transmitted through the drum to the air of the middle ear, and thence directly to the labyrinth, without the assistance in any way of the ossicular chain. Spear[2] states that in many cases the presence of the drum is an actual hindrance to hearing, and shows that the drum may be punctured with impunity. In the case of small open perforations, most excellent results are obtained in his hands by the use of a small disc of absorbent cotton placed over the opening.

The relationship of the facial nerve to the mastoid process has been studied by Joyce,[3] of Dublin, on a series of 30 temporal bones with the following results: (1) The facial nerve lies altogether in front of the mastoid process, and a drill sent straight in from any point on the surface of the latter cannot injure the nerve; (2) in 43.3% of the cases the facial nerve was more superficial than the external semicircular canal, and in an equal number of cases the opposite of this was true; in the remaining 13.4% these structures were the same distance from the surface.

E. Amberg,[4] from a study of 17 temporal bones, is inclined to agree with Trautmann, of Berlin, who says that displacement of the lateral sinus is due to and is indicated by asymmetry of the skull, and that it is usually placed farther forward on the right side.

Okade [38] concludes, from a study of 111 skulls, that one can obtain no trustworthy guide from the anthropological form as to the presence or absence of the so-called danger points in the temporal bone.

Arthur Cheatle,[3] of London, discusses the anatomy of the petrosquamosal sinus, and reports 2 cases in which at autopsy it was found that there had been an extension of the septic process through this aperture.

AURICLE.

Zeroni [5] reports 5 cases of carcinoma of the ear. The diagnosis in each case was confirmed by microscopical examination. The first was an epithelioma of the auricle; amputation, recovery. The second case was an epithelial carcinoma involving nearly the whole temporal bone, with perforation into the cranial cavity. The disease was too far advanced to admit of operation, and the patient died. The third was an epithelial carcinoma of the auricle with swelling of the lymph glands behind the ear, in neck, and one over the clavicle. Auricle amputated, cartilaginous portion of the external meatus, and swollen glands removed; recovery. The fourth was a case of epithelial carcinoma of the auricle extending to the temporal bone; perforation into the cranial cavity; meningitis; death. The fifth was an epithelial carcinoma arising from the middle ear; extension inward; death; no autopsy. All the patients were over forty years old, three over sixty.

Lermoyez [6] describes two varieties of eczema of the ear; the acute, which is usually moist, and the chronic, which is usually dry.

CANAL.

Schwartze [7] has devised an operation for the relief of atresia of the meatus, which consists of detaching the auricle and cartilaginous meatus posteriorly down to the structure, which is then removed, the walls of the canal being slit horizontally and sutured backward, as in the radical operation. He does not ordinarily leave a permanent opening behind the ear. In 11 cases on which he has performed this operation, only 2 were unsuccessful; and it is a significant fact, in view of the poor results generally attending such operations, that in the 2 cases where no bone was removed from the posterior wall of the canal a poor result was obtained. The author naturally makes the suggestion that at least a portion of the bony canal be removed in these cases.

FOREIGN BODIES.

Many cases of injury to the drum caused by too zealous efforts to remove foreign bodies have been reported during the past year. Lermoyez [6] points out that it is the unskilful efforts to remove foreign bodies that does harm, rather than the object itself. "Hundreds of lives might be saved every year if physicians, nurses and parents realized that a foreign body in the ear does no harm as long as it is let alone. Under ordinary circumstances the syringe is the best means of removing a foreign body."

Sturrock [8] has employed suction in the removal of smooth foreign bodies from the canal, using for this purpose a syringe attached to a piece of rubber tubing dipped in glycerine.

Church [9] reports the case of a patient who had experienced pain in the right ear at intervals for two years. Examination showed the ear to be filled with epithelial scales and wax. After removing considerable of this, a large live tick was found embedded next the drum.

In a case where a piece of rubber from the end of a lead pencil had become tightly wedged in an ear, rendering its removal difficult, Macaskie [10] placed against it a string, previously dipped in a strong adhesive solution. This was allowed to remain for twenty-four hours, when no difficulty was experienced in removing both string and rubber.

DRUM MEMBRANE.

Packard [11] reports several cases of traumatic rupture. Sudden condensation of air in the meatus is a common cause of this accident. He calls attention to the fact that at the battle of Santiago, when the men did not have time to take the necessary precautions, many ruptures of the drum membrane occurred; while at the battle of Manila the men protected their ears with cotton, and consequenlty no such injuries were reported.

Richards [12] reports a case of traumatic rupture of the drum caused by a stream of water from a fire hose.

Tuttle [13] saw a peculiar case in which a hairpin had been accidentally forced into the ear of a sleeping patient.

ANESTHESIA OF THE DRUM.

Gray [14] has used cocaine in equal parts of alcohol and anilin oil for the relief of pain in doing paracentesis. The formula he employed consisted of five parts cocaine with fifty parts each of the solvents. He reports very good results from the use of this local anesthetic. (This solution has been tried repeatedly in the writer's clinic with absolutely negative results.—ED.)

AURICULAR CATAPHORESIS.

Ferreri[9] conducted a series of experiments with a current of five milliamperes, one pole covered with felt being introduced into the meatus, the other being applied over the mastoid of the same side. Various solutions were used in the canals, and the results carefully noted. Regarding his observations, the author says: "In conclusion, the various experiments referred to have not demonstrated that, under the action of an electric current, the medicaments applied (either in solution or in gelatine discs) to the tympanic membrane and to the mucous membrane of the cavity are absorbed. The results demonstrate that auricular therapy cannot count galvanic cataphoresis among its efficacious resources."

ACUTE MIDDLE EAR DISEASES.

Würdemann,[15] in an article on "Otitis Media in Children and its Treatment," deplores the general ignorance of the medical profession in regard to recognizing the seriousness of inflammations of the middle ear. Many physicians never look at a sick child's ears, and it is common practice to allow trouble to develop there without any attempt at examination until the ear ruptures of itself. Otitis media is mainly a disease of early life. "If properly treated and seen early enough, acute inflammation of the middle ear seldom or never results in chronic suppuration, and I state with all the emphasis in my power that chronic suppuration of the middle ear is positively the result of either neglect, improper or insufficient treatment."

Barth[1] found, in 600 infants ill with various affections, 80% with a lesion of the middle ear. Many of these cases escape detection during life; the middle ear may be full of pus, yet present no other physical change than a slight convexity of the drum, injection being absent.

Ponfick's well-known tables show that as a result of 100 consecutive autopsies of infants there were only 9 with normal ears.

Randall[16] points out that it is not absolutely necessary to have many instruments for the examination of the middle ear, but that it is the eye and hand of the observer that is all important. He also calls attention to the fact that nearly all experts are on record as to the small value of the watch as a test, and recommends the whisper and voice tests as more practical and satisfactory.

Bishop[17] recommends the use of hot tobacco smoke in the treatment of acute inflammation of the middle ear.

Einis[18] uses glycerine and carbolic acid in the auditory canal as soon as the membrane shows redness.

Boucher[19] is opposed to the hasty performance of paracentesis in acute catarrhal otitis media. When it is done it should be under strict asepsis, and the meatus should be packed gently with a strip of iodoform gauze.

Halsted,[20] in discussing the significance of earache in children, finds that:

(1) Earache in children is generally caused by acute inflammation of the middle ear, suppurative or catarrhal.

(2) Infants and young children may have suppuration in the middle ear without giving satisfactory evidence of pain or without rupture of the drum.

(3) In the absence of other known cause for pain, from which a child is evidently suffering, the first cause to be thought of should be acute otitis media, and this calls for an examination of the drum membrane.

(4) It has been shown by examination of the middle ear during life and post mortem that purulent otitis media is nearly always present in acute infectious diseases of the gastro-intestinal and respiratory tracts in young children, especially in gastro-enteritis and bronchopneumonia, to which diseases it probably stands in a causative relation.

(5) The cause of death in many acute and chronic infectious diseases, in meningitis and in the exanthemata, is the result of unrecognized and untreated abscess of the middle ear.

(6) Repeated earaches in children are ordinarily but a sign of acute exacerbations of a chronic otitis media resulting from adenoids.

(7) In adult life, so-called catarrhal or progressive deafness is often but a final stage of otitis media, which had its beginning in early childhood, when it was due to adenoids, and practically curable.

Leutert-Konigsberg,[39] in a series of bacteriological examinations in cases of mastoid infection following acute otitis media, found pathogenic organisms in the following order of frequency: Streptococcus, pneumococcus, staphylococcus, pyogenes albus and tubercle bacillus. In sinus thrombosis the streptococcus was usually found alone.

CHRONIC NON-SUPPURATIVE OTITIS MEDIA.

Bonnier[21] has noticed that even before a patient is aware that any hearing has been lost, he will hear better by bone conduction.

Lucæ[22] still believes that many cases are benefitted by means of his pressure probe, especially where the disease has not existed too long.

Leavitt[23] has devised an instrument for the use of hot air in the treatment of middle ear catarrh.

Fischerich[24] uses a 2% aqueous solution of pilocarpine injected into the tympanic cavity through the Eustachian tube. This treatment is continued daily for a month, and he considers the results surprisingly good in cases of long-standing sclerosis.

Burnett[9] has removed the incus for the relief of vertigo with complete success in 27 cases. His theory is that the dizziness is caused by an increase of the labyrinthine pressure due to impaction of the stapes in the oval window, without corresponding outward movement of the membranes of the round window.

McCaskey[16] calls attention to the fact that vertigo may be of gastric origin and reports a case

in which, through lavage, etc., the patient made a complete recovery.

Ballenger[25] advocates tenotomy of the tensor tympani muscle for the relief of deafness and tinnitus in certain cases. He gives these three indications for operation: (1) Retraction of the drumhead due alone to shortening of the tendon of the tensor tympani. This is rare; (2) if the focusing or selecting power of the ear is intact, and there is retraction of the drumhead, it is more probable that the operation will be successful than if the focusing power is lost; (3) politzerization, followed by relief of short duration, is sometimes a favorable indication. If the tendon is shortened the drumhead is so forcibly retracted that the air is soon forced from the tympanum — perhaps in a few seconds or minutes. Unfortunately, there are other conditions that will cause the inflation to last but a few seconds; namely, adhesive bands and shrinkage of the ligaments and mucous folds arising in the superior and outer wall of the tympanum, and attached to the head of the malleus and body of the incus. It is not always easy to determine whether the retraction is thus complicated in its origin.

CHRONIC SUPPURATIVE OTITIS MEDIA.

Felt[26] says a suppuration of the middle ear not kept up by necrosis, polypus or a foreign body, is usually chronic because (1) the tissues are lowered in vitality; (2) the septic material is active; and (3) the drainage is poor. When the discharge is profuse he believes in frequent syringing.

Barbee[27] states that a chronic suppuration is always the result of neglect or of improper treatment during the acute stage.

Oaks[28] states that cholesteatomatous masses may be prevented from accumulating by the instillation of boracic and salicylic acids in alcohol. When the mastoid is involved, the earlier it is operated on the better.

Richards[29] believes in capillary drainage in the treatment of both acute and chronic suppurations of the middle ear. In case the patient cannot be brought to the office sufficiently often for this treatment to be administered by the physician, he directs some member of the family to use dry treatment for the ear. He prefers gauze to absorbent cotton, and is not in favor of having the ear syringed at home.

Phillips[30] advocates the use of pure carbolic acid in the treatment of chronic suppurative otitis media, and in cases where purulent processes have involved the mastoid. He leaves the acid in contact with the tissues from thirty to sixty seconds, and then applies alcohol as an antidote.

Fleming[9] reports a case in which a growth filling the external canal was treated for six weeks without materially altering its condition. Microscopic examination showed the mass to be a true fibroma, and the patient finally consented to enter the hospital for its removal. After making a post-aural incision, the growth was snared out and the base cauterized. In about two weeks free granulation tissue began to develop in the tympanic cavity, necessitating further curettement.

MASTOID.

McKernon,[12] after a comparative test of the value of heat and cold to abort inflammation of the mastoid, has concluded that cold is by far the better. His usual method of treatment is to leave the cold against the mastoid for twenty-four hours, and then if the tenderness has not entirely disappeared it is reapplied for another twelve hours. If there is still no improvement he operates without further delay.

Dench[31] advises early operation in all suspected cases of mastoiditis, and lays stress on the fact that operation is absolutely harmless.

H. Knapp[32] states that mastoiditis is quite frequent in children, and that it is much more difficult to obtain a successful result following operation than in adults.

Oppenheimer[15] finds that percussion of the acutely inflamed mastoid is of no value as an aid to diagnosis, because light percussion does not produce any sounds that can be compared with the normal side, and when deep percussion is tried the pain is too great. Furthermore, dulness does not indicate the presence of pus, as the same sound may be obtained when edema or sclerosis are present.

Among recent operative procedures on the mastoid is that of Küster,[33] whose method is as follows: An incision is made downward behind the auricle, continued posteriorly across the tip of the mastoid, and then upwards as far as the top of the original incision, giving a U-shaped cut. The periosteum is pushed aside slightly, and with a small chisel and mallet the same outline made in the bone, which is then pried up, leaving the outer shell of the mastoid attached to the superficial tissues. After opening the antrum, this is turned down again, a small notch being made in the lower part for drainage. It is claimed that the superiority of this method lies in the fact of its giving quicker healing, and resulting in a smaller deformity.

Grunert and Zeroni[34] have both observed the frequency with which mastoiditis is caused by the use of the nasal douche.

Ballance,[35] in the treatment of acute cases, believes that only the antrum and any cells which may be suppurating should be opened, but that the tympanum and meatus should be left undisturbed. On the other hand, in operations for the cure of chronic otorrhea, the simple opening of the antrum can be of little value.

SINUS THROMBOSIS.

McKernon[36] has presented during the past year an exhaustive study of this subject, together with the report of seven cases. In all cases he believes in thoroughly exposing the sinus, and then in aspirating, to determine the presence or absence of fluid blood.

Viereck[1] believes that ligation of the internal jugular vein should always be done before opening

the sinus, as it is much more certain to prevent pyemic infection.

Randall[37] is inclined to believe that ligation is not necessary in all cases, and urges the importance of rapid operating. He considers the diagnosis a most difficult one to make.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

F. G. BALCH, M.D., SECRETARY.

Regular meeting, March 6, 1901, Dr. F. S. Watson in the chair.

Dr. Watson: It gives me much pleasure to present to the society a gentleman who has, as most of you know, done such admirable work in advancing our knowledge upon the subject of renal tuberculosis and tuberculosis of the genito-urinary organs in general—Dr. F. Tilden Brown, of New York.

Dr. Brown read a paper on the

DIAGNOSIS AND TREATMENT OF RENAL TUBERCULOSIS.[1]

Dr. Arthur T. Cabot: Dr. Brown's paper seems to me exactly the sort of paper that is called for in the present position of this subject. The time is still too early for us to adequately weigh the claims of surgical interference, to decide on the kind of case in which surgical interference does the most good, and in which hygienic treatment may be tried. The cases of nephrectomy in early renal tuberculosis are certainly very encouraging as far as I have seen them in reports, and as far as I have known them in cases in this neighborhood. It is certainly true that the disease often attacks one kidney first, and for a considerable time remains confined to that organ, and only after it has really made great progress in that kidney, reaches over to the other. It seems, therefore, as if surgery probably had a very hopeful field in those cases of early tuberculosis in which, by the methods of accurate observation which Dr. Brown has described, the disease is discovered early. I think that the medical side of the subject should have also a great deal of careful observation, and is, perhaps, in danger of being neglected. A medical man sees a case of renal tuberculosis, sends the patient to some health resort, to the Adirondacks or Colorado, or into the country somewhere. He does not afterwards take the interest in that case that a man who had taken out the kidney would. He does not follow such cases with sufficient closeness to give us the real life history of those that are so treated, and yet it is very important that that life history should be known. We constantly see cases in which we feel that the disease has progressed so far as to make the operation of doubtful use. The disease may have already affected the bladder or the prostate in man; there may be doubt as to the other kidney; and to enable us to judge of the proper treatment of those cases, we ought to know exactly how much value there is in hygienic treatment. It is very important, then, that we should report our cases in this sort of way, illustrated by Dr. Brown this evening: the cases that are cured, and the cases that are not, and the cases in which different operations are done, whether they are successful or not. It is only in this way that we can accumulate the statistics on which we can form adequate judgment in this important subject — one of the very important subjects on the border line between medicine and surgery.

Dr. Brown, in one or two of his cases, spoke of the variations in size of the kidney, getting large, and then getting small again and less painful. This is seen not infrequently in connection with tuberculosis. In some cases, no doubt, a diminution in size is due to a tuberculous focus having opened into the pelvis, having obtained sufficient drainage to quiet down the inflammation which accompanied its formation. I think those cases where but one kidney is affected, and that kidney behaves in this way, are just the cases where we are perfectly clear of our diagnosis, and in which the operation has its best field, for such behavior shows the kidney to be very seriously diseased. With such a history, if the other organs have not yet shown evidence of disease, a nephrectomy is distinctly the operation which should be selected.

I think we must not be too dependent upon the demonstration of bacilli in making our diagnosis. As Dr. Brown has shown in his case, a kidney very

[1] See page 513 of the Journal.

decidedly diseased may deliver no bacilli in the urine. We must, therefore, often suspect the disease, even if we cannot prove it by the demonstration of the etiological factor. In such cases we have in the tuberculin test a valuable means of learning the nature of the disease. If the evidence from this test is positive as to the existence of tuberculosis somewhere, and yet leaves one in doubt whether the kidney is the seat of the disease, it is to be remembered that an exploratory incision down to the kidney is not a dangerous procedure, and is quite justifiable in a case of suspected disease, even if not proven.

I should like to ask Dr. Brown about the invagination of the ureter which he described; if he has seen that method used, and if it was a distinctly hopeful procedure. In the few cases where, after removal of the kidney, decided frequency of urination remained, it would be interesting to know if the prostate was absolutely free, and if the mucous membrane of the bladder showed any tuberculous involvement.

The catheterization of the ureter is an extremely valuable procedure, and helps us immensely in many cases. In the female the slight experience I have had with the Harris segregator has made me have a considerable feeling of confidence in that instrument, in giving us very good evidence of the relative condition of the two kidneys. It is easily used in the female, and I have thought that method was a useful one. We can apply it to cases with much less difficulty, and with less discomfort to the patient, than the catheterization of the ureters. I am inclined to reserve catheterization for the cases in which the evidence from the separator has not been very conclusive.

I have been very much interested in the paper, and it seems to me an excellent example of the kind of reports we ought to have from men having many cases, and men having few cases, in order to learn the truth of this matter.

DR. ALFRED WORCESTER: I never was more aware of my ignorance and presumption in attempting any discussion than I am this minute. Those of us who have only a few such cases in a lifetime are not able to report them with anything like the thoroughness shown by the reader tonight in the report of his cases. We do not know enough to report cases in that way, and I do not suppose the general practitioner will ever be able to report his cases of renal tuberculosis in such shape that the surgeon will receive much benefit from his reports. I am, however, exceedingly interested in the general subject of tuberculosis, although I know almost nothing about the special subject of tuberculosis of the kidney. The few cases I have had I have blundered into. The first one where I attempted to do nephrectomy I got scared after having cut down upon the kidney. By the time I had made up my mind it was tuberculous, it came over me that probably the other kidney was also tuberculous, and that I better depend upon permanent drainage. The man with his sinus has for the last few years been earning his living and supporting his family. I do not know whether he would be better had I taken that kidney out.

I never shall be able to catheterize the ureters in the male patient. It is the height of my ambition to be able to do it in the female. It needs a man with special opportunities and tremendous application in that special direction to be able to catheterize the male ureter.

I have been particularly delighted to hear Dr. Brown's mention of the use of tuberculin in establishing the diagnosis of tuberculosis. I remember a few years ago insisting on the reasonableness of that procedure, and I also remember how chilly and terribly still the meeting became. I have employed that measure in cases of suspected tuberculosis, and am perfectly convinced it is a sensible, reasonable thing to do. Any practitioner is able to do that. It sometimes is an immense relief, and especially in eliminating suspected tuberculosis. There is nothing I have ever been able to do in my practice that has given me anything like the satisfaction I have had in giving tuberculin to patients with suspected tuberculosis and after so finding they had not tuberculosis, in seeing their general symptoms improve as soon as they were assured they had not the disease which specialists had told them they probably did have. What I want to bring particularly to the front is the danger of considering tuberculosis merely a local disease. Tuberculosis of a joint, kidney, bladder, lung, is so apt to mislead the practitioner into thinking all he has to deal with is a local lesion, whereas tuberculosis is essentially a general disease, seldom existing solely in one particular part of the body. Instead of there being any predisposition to tuberculosis, I wish we could feel that predisposition to tuberculosis *is* tuberculosis, and that the disease generally begins very early, and at different ages there are different manifestations of it. Just as soon as we get into our heads the idea that in tuberculosis of the larynx, lungs, kidney, bladder, joints or lymphatic glands what we have present is but the local manifestation of a general disease, then we shall come nearer to the desired pulling together of the lung specialist and throat specialist and aurist and genito-urinary specialist and the orthopedist. The poor, distracted family now has to go first to one and then to another specialist, instead of having from the first, as soon as the evidence of tuberculosis was discovered, some general treatment directed to the extirmination of the disease. I am sick and tired of the much-vaunted hygienic treatment of tuberculosis, as if that were all that ought to be provided. Hygienic treatment means nothing more than is necessary in the treatment of any disease,— good food, fresh air and rest and exercise and all that sort of thing. Of course we need hygienic treatment, but we need something more. I am perfectly satisfied that we shall find the proper remedy for tuberculosis in some of the tuberculin derivatives. I have, perhaps, been unduly enthusiastic; but there are some things certainly true about it. Tuberculin is an absolutely reliable diagnostic test of the presence of

tuberculosis. That is a fact, and something that as yet general practitioners do not avail themselves of. We know that the early recognition of tuberculosis is of immense importance, and yet only one general practitioner here and there will avail himself of that certain test. It is equally true that a patient suffering from tuberculosis can be immunized to tuberculin. A patient who reacts to tuberculin at first will not react to the same dose of tuberculin, nor to ten times that dose if treated steadily with slowly increasing doses of tuberculin. Now those of us who have immunized patients in this way believe that we have seen them improve as they would not have improved under merely negative hygienic treatment. I believe that that is the right way of attacking cases of tuberculosis; and all the different sanitariums, all the different hospitals, all the different dispensaries where the hygienic treatment alone is depended upon, are to my mind just wasting time. I still believe that in the wards of the Charité the best work on earth is being done against tuberculosis. There are a good many reasons why the use of tuberculin meets its present disfavor; one of the reasons, however, is unworthy of the profession, and that reason is the ignorance of the profession with regard to the proper use of tuberculin. The profession grabbed at it, used it wrongly, and then condemned it, and has never yet been willing to take up its intelligent use. It is a very different thing to use it properly. The profession used to give ten or even one hundred times the proper dose, and indeed until Prof. Theobald Smith discovered how to standardize tuberculosis, no one could be sure of what dose he was giving. Another reason which has lately been made apparent to the profession why tuberculin should have given such discouragement in its early use, is found in the fact that there are different kinds of tubercle bacilli.

We are again indebted to Professor Smith for this discovery. Until recently, Koch himself thought that the bovine tubercle bacilli were the same as the human tubercle bacilli; but now we are told that there are at least four different varieties of the tubercle bacilli easily distinguishable; and there is considerable doubt whether there was ever a case of human tuberculosis contracted from either milk or beef, for there is such a difference between the bovine tuberculosis and the human tuberculosis as to make it at least very questionable if the disease is ever communicable from man to cattle or from cattle to man; and, moreover, the tuberculin derived from these different varieties of tubercle bacilli is very different in its effect upon the human subject. The tuberculin derived from the bovine tubercle bacilli has a very different effect upon the tuberculous patient from tuberculin derived from cultures of the human tubercle bacilli; so all the early experimentation with tuberculin is in the very foundation at fault, because we did not know with which tuberculin the experiments were made. Now it is possible to obtain tuberculin from the human tubercle bacilli or from the bovine tubercle bacilli, and you can use one or the other, and you can, in using first one and then the other, produce reactions in the human patient quite as distinct and different as smallpox is different from vaccination. Experimentation on animals has proved that a small amount of tubercle bacilli of the bovine form will kill a strong steer, whereas, ten times the dose of human bacilli will hardly hurt a weak calf. Of course we cannot try the counter-experiment of the deadliness of the bacilli of the two varieties on the human patient, but I have not the faintest doubt if we could try that experiment we should find similar results. I can hardly expect surgeons to be interested in such reflections. I am, however, quite unable to understand the apathy of my brother practitioners in medicine; and I cannot help thinking that there never will be a real forward step taken in the treatment of tuberculosis of any special form, renal tuberculosis, for instance, until the profession, as a whole, is willing to stand fairly facing the fact that tuberculosis is never a local disease, but always a general disease; and that the proper treatment of it, while, of course, the surgical evacuation of an abscess is necessary and the curettage of the tuberculous ulcer is necessary, — the real fundamental treatment of tuberculosis is, of necessity, medical now and always.

Dr. Paul Thorndike: It is interesting to come to a meeting of the surgical section and to hear what is commonly considered a surgical topic discussed so largely from the medical aspects of the case. Most of us who have been surgically educated have been brought up in the belief that tuberculosis is a disease for the surgeon to palliate, but not to cure; that the surgeon needs a surgical indication before he interferes. Of late years, with good cystoscopic work, with Dr. Brown's work on ureteral catheterization, with the constantly increasing accuracy and ease for making an early diagnosis, we are constantly confronted with the reports of cases where kidneys have been removed because they were tuberculous, although other surgical indication was often lacking. The diagnosis of the disease resulted in the operation. We make, occasionally, an early diagnosis of tuberculosis of the kidney, and are inevitably confronted with that diagnosis and its possible consequences, as the only indication for operation. That happens to all of us, I am sure. What we want to know is, what is the alternative if we do not operate? What we want to know is, what is tuberculin going to offer us; what is hygienic treatment going to offer us? What can we do for our patient if we do not operate? That is renal tuberculosis today as it looks to me.

Dr. Otis: I have had but trifling experience in renal tuberculosis. My studies in tuberculosis have been in another direction. There are two questions, however, I should like to ask Dr. Brown: (1) Through what channels the tuberculous infection is conveyed to the kidneys; and (2) by what means he thinks climatic treatment

benefits renal tuberculosis — in any special way, or only by the general effect? I suppose in many cases there is coincident pulmonary tuberculosis, and by the beneficial effect of climate upon the latter, the renal tuberculosis is also favorably influenced.

DR. RICHARDSON: I have been very much surprised to hear two things said here tonight: one, that tuberculosis is a constitutional disease, and the other that the surgical treatment of localized tuberculosis is palliative. I have always supposed (1) that tuberculosis in many of its forms, at least, is a purely local disease, its only constitutional manifestation being due to the absorption of toxins; and (2) that the removal of its focus by surgical means will in many forms effect an immediate, complete and permanent cure. I have been very much interested in this paper, especially in the cases. It has always seemed to me extraordinary that tuberculosis of the epididymis, for example, of the urinary tract generally, outside the kidney, is so obstinate — indeed, almost invariably fatal, even after most thorough operation — when the most extensively disseminated miliary tuberculosis of the peritoneum will, after trifling incision, result in permanent cure in at least half the cases; that tuberculosis of the larynx is so obstinate, while removal of a tuberculous gland in the neck ensures, in most cases, immediate and permanent recovery.

I can add but little to this discussion from my own experience. I can add three cases of renal tuberculosis operated upon and one not operated upon. All these cases have followed the usual course of renal tuberculosis, which — like tuberculosis affecting the testicles, the vesiculæ seminales and the bladder — is a very unpromising disease, whether operated on or not. I have never seen the least benefit come from operation. I have removed three kidneys for tuberculosis, as demonstrated by Whitney, Wright and others. No good whatever was done. One patient died as the result of the operation. In another case I was able, after first removing tubercular Fallopian tubes, to palpate both kidneys, and get a very good idea indeed of their outline and condition. I removed the left kidney and the left ureter. The tubercular process extended downward as far as I could go. The patient recovered well from the operation, but died in the course of a few months of pulmonary tuberculosis. A few months ago I removed a kidney, in which case there was ascending tuberculosis of the kidney. The patient had frequent and painful micturition. The operation was in itself very successful, and there was great temporary improvement. I hear now that the frequent micturition which was benefited apparently by the operation has returned, and the patient is now going down hill. I should welcome any means of earlier diagnosis in renal tuberculosis. I believe, with Dr. Cabot, that exploration of the kidney is easy and safe. I have explored a number of kidneys in this way, some by nephrotomy, some by digital exploration previous to nephrectomy, and I have been much impressed by the facility, safety and efficacy of the procedure.

DR. ELLIOT: I have here a drawing of an early case of tuberculosis of the kidney which I will show, as it serves the purpose of what I am about to speak of. This case was of a girl nineteen years old, and the operation was done six months after the first symptoms. (The water-colored drawing showed a kidney in the early stages of tuberculosis.) We surgeons have to come down in our present knowledge from the constitutional treatment which *should* cure the patient to taking care of a degenerating localized lesion, of an abscess cavity. When you look at that drawing and see not one cavity only, but other centers, little cheesy patches breaking down, it seems to me very improbable that either the tuberculin or any other treatment will relieve surgeons of attacking the tuberculous kidney. I think this subject is a very important part of surgery, and Dr. Brown has given us the very latest and most advanced ideas on the subject. I have profited much from what he said, and am delighted to have been present. I believe that exploratory incisions will be made less frequently in the future. As these methods Dr. Brown is practicing become more generally understood and more generally practiced the necessity for exploratory incisions will be less, although probably not wholly done away with. Dr. Brown has spoken of the value of catheterizing the ureters, and I have no doubt it is great. He also showed us a specimen which clearly shows that in that particular case catheterization of the ureters alone would have led to a wrong supposition of the state of affairs. I have recently had a case in which it was very difficult and very puzzling to know what to do on account of the result of the catheterization of the ureters. Both ureters were catheterized, and there was pus in both urines and tubercle bacilli in both urines; the animal inoculation was positive from both kidneys. That result put me off from doing nephrectomy. The patient was treated hygienically and improved so much, looked so well, that it seemed wise to take out the kidney, which was evidently enlarged. A nephrectomy was done with a very good result, and the other kidney has worked very well since the operation. We may meet either of the two following conditions: You may find from your catheterization tubercle bacilli in both kidneys. You then have to decide if your patient will be benefited by removing the kidney most diseased. You may not get the bacilli in the early stages of the disease, because the tuberculosis does not begin in the pelvis of the kidney, it begins in the substance of the kidney, and the abscess may not have broken through; considering both these situations, it seems to me we are in danger of overvaluing the results of catheterization of the ureter. For after all, it usually comes down to the fact that if you have an enlarged kidney on one side, with pus in the urine and tubercle bacilli, that kidney is probably the origin of the disease. If the other kidney cannot be felt, and if you make a cystoscopic examination and find the ure-

ter of that side puffy and with a little ulceration about it, the evidence becomes overwhelming without catheterization of the ureters. I myself believe, in spite of all the enthusiasts say, that it is not a good procedure to catheterize the ureters of a patient about to have nephrectomy done. I believe, from what we know about the difficulties we have following manipulations of the genito-urinary tract, that catheterizing the ureters should not be done without a very good reason for it, not be done unless something hinges on it, certainly not done for curiosity. It seems to me the practical value we are going to get out of it is beginning to narrow itself down. I do not mean to say it is not invaluable in a good many cases, but I do say it ought not to be done simply as routine.

Dr. Munro: With Dr. Brown's deductions I am heartily in accord. I would like to emphasize, however, the climatological side, because I think it is important. A number of years ago I corresponded with all the members of the Climatological Association, and since then I have talked with a good share of them on the subject of their clinical experience in the treatment of genito-urinary tuberculosis climatologically. My deductions have been stronger and stronger every year that those men see most excellent, most complete, results in the treatment of genito-urinary tuberculosis climatologically. I absolutely dissent from Dr. Worcester's statement that climatological treatment is primitive and an old-fashioned method. I believe it is the most important form of treatment we have outside of surgical treatment where surgical treatment is applicable. There is one other thing that ought to be emphasized, and that is, that climatological treatment does not mean simply sending a patient at random out West or to some health climate for one or two or six months, but to a well-selected climate and to a physician who understands the treatment of tuberculosis from the beginning and follows up the patient day after day and week after week throughout his entire treatment; who regulates his rising in the morning, his going to bed, diet, exercise, everything, and has as complete control over him as over his cases of pulmonary tuberculosis. Furthermore, cases that go for climatic treatment ought not to come back in one or two months. They should go for a year or five years or more if necessary, and should never come back to an unhealthy climate until the physician in charge is absolutely satisfied that they can come back tentatively for a summer and then perhaps for a summer and winter, etc. I believe that is the part of the treatment in which we are more apt to make mistakes; namely, the proper and thorough and really scientific treatment of these genito-urinary cases by climatic methods.

Dr. Craig: I have the permission of Dr. Baker to report a case of his very recently operated upon, and whose life history as regarding the tuberculosis is just at its beginning. The patient, a girl of sixteen, was referred to him by a suburban physician about nine months ago, with a very intractable cystitis. Cystoscopic examination showed an open ulcer just within the bladder, near the urethra; and after local treatment failing entirely, the bladder was opened through the vagina, and the area, including the ulcer, was excised and a vesicovaginal opening was left, and through that opening the bladder was treated regularly, with the result that all bladder complication, so far as any objective signs went, was cleared up. She had no pain, never manifested lumbar pain. She had not gained beyond a certain point, and on certain nights, showing no particular regularity, there was an evening temperature. She returned to the hospital and the ureters were catheterized, as renal tuberculosis was feared. The urine from the left kidney proved negative. The urine from the right kidney showed pus and bacilli. Two weeks ago the kidney was removed. The ureter was removed down to the bladder, by making a series of incisions through the peritoneum and over the course of the ureter, the ureter being drawn under the peritoneum, and it was removed down to the bladder and was there cut off. In regard to the removal of the ureter, I have not heard Dr. Brown's answer to Dr. Cabot's question as to whether he has tried the inversion of the ureter, but I cannot conceive of the inversion of this ureter having been possible, because the upper end of the ureter was not particularly sacculated, but extremely thick and cord-like and very rigid; whereas, as we approached the bladder, got below where the ureter crossed the vessels, the ureter became practically its normal size; and it would have seemed to me to have been impossible to have invaginated the thickened portion by any means into the normal part and turned it out through the bladder. The patient is sitting up today for the first time.

Dr. Watson: I am entirely in accord with what Dr. Cabot and Dr. Munro have said as to the desirability of a conservative judgment with regard to the operative treatment of renal tuberculosis. The testimony with respect to the results of non-operative treatment offered by physicians is meagre, because of the difficulty of following the cases for sufficient periods to allow of a sound judgment. Moreover, if I may judge from my personal experience, it is safe to say that the majority of medical men — a large majority — do not know what is meant by early recognition, and properly carried out conservative treatment, in the sense of hygiene, climate, diet, etc. So far as I have had the opportunity to note its results, I have received the same impression as Dr. Munro; that they are much more favorable than we as surgeons are inclined to believe; and while in no wise wishing to minimize the successes of surgical intervention, I think the conservative views expressed here are well taken and timely. I cannot agree with what Dr. Cabot said as to the value of a lumbar exploratory operation in cases in which the diagnosis is obscure, for mere palpation and inspection of the kidney will very rarely give us information that we cannot better obtain by the cystoscope, and ureteral catheterization

used in connection with it after the method employed by our guest, Dr. Brown.

It does not seem to me that Dr. Elliot's assertion is justified, in which he maintained that it was useless to look for any benefit from means other than surgical in such a case as that which he described, for we know that tuberculous lesions which are of equal or greater extent elsewhere in the body are capable of arrest under non-surgical treatment, and it is too much to assume that the same may not be true of the renal lesion which he referred to.

Two statements made by Dr. Worcester should, I think, be modified somewhat. They are: "That tuberculin treatment was not employed in sanitariums," and "That tuberculin as a diagnostic test is infallible." At the Adirondack Sanitarium of Dr. Trudeau, treatment of selected cases — afebrile and well-nourished patients — by modified tuberculin is employed systematically in a number of cases — in the last annual report there were 19. With regard to the diagnostic infallibility of the tuberculin test, we know that several diseases other than tuberculosis may give the same reaction that is supposed to be characteristic of the latter malady, and also that there are instances of tuberculosis in which the test is not followed by the reaction. Yet one cannot but cherish the hope that by means of tuberculin, in one or another of its modifications or varieties, there will yet be found a specific remedy for this most widespread of all the diseases that we know in our part of the world, the step to actual discovery seems to be but so little removed and the results of the study already are so very suggestive of the possibility of success.

The paper of Dr. Brown to which we have listened furnishes another example of thorough, well-considered bits of work for which he has been conspicuous in this and other fields of surgery, and is a vindication — if one be needed — of the specialist, to whom alone we are indebted for such advance in our knowledge and the ability to practically apply it. I wish to express the thanks of the society to Dr. Brown for his kindness in coming here, and for the valuable and interesting paper to which we have had the pleasure of listening.

DR. F. TILDEN BROWN: As to the management of the ureter brought up by Dr. Cabot and referred to by several other members. It is my idea in nephrectomy to remove as much of the ureter with the kidney as the particular wound will permit of, whether the ureter is at fault or not; if we can appreciate — we usually can — by the finger that the ureter is diseased, we will extend the incision downward and secure as much ureter attached to the kidney as possible. It has been my idea, and I am not ready to give it up, that the diseased ureter left goes into a kind of functionless decline, and that it is no longer so much of a menace in spreading disease to the bladder, and also probably less of a menace in disseminating disease by the blood to other parts. However, all of the diseased ureter which is available should be taken out at the same time that the kidney is removed.

As to the disease being limited to the upper part of the ureter, I am not prepared to say. My limited experience rather supports that view. Where cases show a marked hyperemia or even ulceration at the ureteral mouth in the bladder, I am not prepared to believe that it indicates a continuous tuberculous ureter from the kidney down to that point. I have an idea that there may be a great deal of intervening ureter in a practically normal condition.

As to the passage of the ureteral catheter with chromic gut in it before operation, with the hope of fixing the upper end of the ureter for invagination, it is unnecessary to say that there is no reason to think that this would be available in a great number of the cases for getting rid of the ureter. There are, however, some cases where we may infer from previous ureteral catheterization that this canal is unusually patulous, and in which it would be roomy enough to permit of invagination. In one case, the picture of which I pass, where the kidney was removed with seven inches of ureter attached, I think the remainder could have been managed in this way; for, although lined with tubercles and dilated, it was perfectly flaccid and soft. I have only suggested the process as a possible means, in some cases, of saving what seems a tremendous wound for a somewhat questionable end.

As to the persistence of frequency in two of our cases of nephrectomy, Dr. Cabot asked about involvement of the prostate. One of these patients was a woman. In the case of the man I cannot answer the question. These curtailed notes contain nothing as to his prostate; but as I recall it, he had no such involvement.

Dr. Worcester's intimation that catheterization of the ureters in the male is a difficult procedure, I would say that in the majority of cases it is not, when done with a systematic degree of patience. Of course, everything must be right at hand, and all the details must be prearranged; but, as far as the difficulty of introducing the catheter into the mouth of the ureter, it is generally simple, and it is a procedure that will be used more and more. At this moment I might skip a little, and in reply to Dr. Elliot's strictures upon the process, say that we agree with him that it is not a matter of overwhelming importance; but it is only one additional way of getting good evidence as to existing disease in one or the other kidney. So far as its being injurious, I have yet to see proof. It certainly is not to my mind as rough a procedure as the employment of a searcher in patients with symptoms of stone or enlarged prostate. The reaction following such examinations is often greater, and perhaps more dangerous, than the careful use of the cystoscope, and the introduction of ureter catheters, which, unless there is some reason for it, I never pass more than two and a half inches. I would say, while on this subject, that if we accomplish anything surgically in renal tuberculosis, it seems that it must be done during the

early stages of the disease. If we wait until the striking subjective and objective symptoms occur, we are very apt to have waited until the disease has passed pretty well into the ureter, the bladder, or posterior urethra. It does not appear to be advancing the subject to belittle any of the methods of getting at an early diagnosis, even if such a method is not always successful; and we certainly do not claim that it is so.

As to Dr. Worcester's theory, that tuberculosis is a general disease, I am quite in accord with what several of the speakers have said on this subject. I am much pleased by Dr. Worcester's statement, that he sees, from what tuberculin has shown in the past, hope that it will yet assume a form for successful treatment of the disease.

I was asked through what channel I thought tuberculosis disseminated. We all recognize the blood as one medium. I think this is the most common way by which the kidney becomes implicated originally. Of course, when the disease is far advanced, very commonly the other kidney is reached by a descending tuberculosis, in lymphatic continuity to the bladder, and up to the other kidney, as is seen in this illustration, although there is no reason why the second kidney should not receive a subsequent infection through the blood, just as the first one did some time previously. Again, superficial implantation by the descending bacilli must at times occur.

In what way is climatic influence supposed to be beneficial? This, I am not ready to answer, other than that it is due to a general systemic invigoration. We all know that some tuberculous patients will be greatly benefited by visiting a new place, and a while later they may begin to decline; then going to some different climate again, get a temporary brace, until that, in turn, ceases to benefit. With each move there is a noticeable gain, but if their whole record is reviewed for some years, it may show a decidedly total decline. Such are the cases that are marked for a fatal termination.

I was very much interested in the beautifully illustrated case of nephrectomy, reported by Dr. Elliot, of early renal tuberculosis, and think, from the picture, that it was just the kind in which a happy issue is to be expected from surgery, if from anything.

How much value to attach to the inoculation of animals; that is, how much value has a negative injection of urine, in which tubercle bacilli were believed to have been found? If it were voluntarily passed urine, I should be pretty positive that the bacilli were not tubercle bacilli. If, on the other hand, the bacilli seen by microscope had been collected by the ureter catheter directly from one kidney, I should be quite as positive that they were tubercle bacilli, and that, for some reason, the guinea pigs had not responded to this particular kind; because, although I have seen it stated by several authors, I am not prepared to believe that the smegma bacillus can be derived from the field of a pyelitis. If these authors mean that cases of tuberculous pyelitis are more apt than healthy persons to have conditions about the glans, penis, or about the vulva, favorable for the excessive growth of smegma bacilli, that is another thing.

The Harris segregator I do not like to say much about, because I have not used it much. Of course, one is apt to favor what one uses most. In the Harris segregator one is certainly deprived of the great value which attaches to a visual inspection of the bladder. With the ureter cystoscope you can see the vesical conditions, and those existing around the ureteral openings, and see your catheter go into the ureter; and then, after collecting the renal excretions, see that the catheter comes out of the ureter, so make doubly sure that it has been where you supposed. I don't think there is much question that the ureter cystoscope invites a lesser traumatism than the Harris instrument. I do not use the Kelly method. My cystoscope is on the order of the old, original Brenner cystoscope. It has two barrels below the ocular apparatus. I have had so much satisfaction in the use of this double-barrel cystoscope, I am having another made with three channels, so that when a catheter is in each ureter, the third channel can be utilized in some cases to wash out the bladder, in order to get a specimen for examination; and in all cases, to let off the distending fluid when the catheters are in place.

The ureter catheters I generally use are known as Kelly's, and sold by Kuy-Scheover Co. They are short, and so flexible, that the mouth of the ureter is not put to any tension when the cystoscope is turned towards the other ureter to pass the second catheter; whereas, the European catheters are so stiff, that they would involve a considerable leverage on the ureter in doing this.

ASSOCIATION OF AMERICAN PHYSICIANS.

Abstract Report of the Sixteenth Annual Meeting, Held at Washington, D. C., April 30, May 1 and 2, 1901.

FIRST DAY.

The meeting was called to order by the president, Dr. Wm. H. Welch, at 11 o'clock.

In his opening address he said that, as this was the first meeting of the association in the present century, he felt tempted to review of the past and to forecast that of the future, but the limited time at his disposal precluded the possibility of entering upon such a broad field. He devoted a short time to a consideration of the opportunities at present afforded in this country to those who take up one of the medical sciences as their life work, such as anatomy, physiology or pathology, as compared to the opportunities open to those who desire to fit themselves for the higher positions in clinical medicine or surgery. He thought that we now possess in this country, while far from enough, still, a fair number of well-equipped laboratories representative of each of the fundamental medical sciences in which the training compares favorably with that to be found anywhere in the

world. Laboratory training has in a few years advanced from the weakest to the strongest point in our curriculum. The young man who chooses for his career one of the scientific subjects can find plenty of opportunity in this country for study, and after he wins his spurs can look forward to securing a teaching position or the directorship of a laboratory within a reasonable time, which is a gratifying advance over former conditions; but corresponding opportunities are not offered to those who take up clinical medicine and surgery. The only path open to them is through family practice or dispensary work, and while the desired end may be reached, Dr. Welch thought it was not a method adapted to securing the best results. The contrast was shown in considering two particular points, namely, that there is not the same opportunity for prolonged training under competent supervision; and secondly, that there is little chance that the man who has acquired a high reputation in one place will be called to another while the present organization of schools and hospitals continues to prevail.

In considering the question of the present membership of the association and the fact that it has about reached the limit, Dr. Welch recalled and endorsed the suggestion once made by Dr. Da Costa that a free use of the honorary membership should be made so as to transfer to that list some of those who are now on the active list, but who are prevented for some reason attending the meetings regularly and contributing to the scientific work of the society. Dr. Welch then paid fitting tributes of respect and loving memory to those members who had died within the year, a list which includes the names of Drs. Whittaker, Da Costa, Busey and Draper, all founders of the association and three former presidents.

DR. H. A. HARE, of Philadelphia, read a paper entitled

AN UNDESCRIBED CARDIAC SOUND.

He said it seemed impossible that any heart sound had gone undescribed, and yet he could find no reference in the literature to the one he was about to speak of. It consisted of "a peculiar vibrating sound occurring with the systole, and heard best in the area extending from one inch to the right of the sternum to one inch to the left of the nipple, on the nipple level, and which is sometimes so dry, if I may use such a term, that I have at times considered it somewhat like the pericardial friction sound heard in pericarditis near the base." He was convinced that it was not a friction sound and believed it to be due to the vibrations in the cordæ tendonæ produced by imperfect contraction of their muscular attachments, as he had never met with it except in cases of general debility with feeble, irritable heart. He had found it frequently in early cases of pulmonary tuberculosis and also in the general systemic and cardiac feebleness of influenza convalescence. He compared it with the sounds that this description might suggest, and determined that it was not like any of the known, described sounds.

DR. OSLER said that he did not know that he had ever heard the sound Dr. Hare referred to, unless it was one of those peculiar heart sounds that had sometimes both worried and puzzled him.

DR. W. S. THAYER, of Baltimore, described the

FREQUENCY AND THE DIAGNOSIS OF THE FLINT MURMUR IN AORTIC INSUFFICIENCY.

"In 1862 Flint called attention to the occasional occurrence in uncomplicated aortic insufficiency of a presystolic murmur limited to the region of the cardiac apex; the sound was loud and blubbering, and had all the characteristics of a mitral presystolic murmur. His explanation was, that in cases of considerable aortic insufficiency, the left ventricle is rapidly filled with blood flowing back from the aorta as well as from the auricle before the auricular contraction takes place. The distension of the ventricle is such that the mitral curtains are brought into coaptation, and when the auricular contraction takes place the mitral direct current passing between the curtains throws them into vibration and produces the murmur." It appears that the majority who have recognized the Flint murmur have agreed in considering it of unusual occurrence, Guiteras alone expressing the belief that "Obstructive functional mitral murmurs are of frequent occurrence in aortic regurgitation."

In view of this and of the fact that he had seen a good many cases with Flint murmur in the Hopkins Hospital, Dr. Thayer thought it advisable to analyze the clinical and pathological records of all cases of aortic insufficiency that had come to autopsy in order to reach some conclusion in regard to the frequency of the murmur and its diagnostic features. In 74 cases that have come to autopsy since May, 1889, the records show in 45 a murmur exactly similar to that characteristic of mitral stenosis, at some time during the observation of the case. In 12 of these there existed a mitral stenosis in connection with an aortic lesion. In 33 cases in which the Flint murmur was observed, the condition of the mitral valve, beyond the dilation of the orifice usual, as a rule, in well marked aortic insufficiencies, was absolutely normal in 17 instances; that is, the majority of the uncomplicated cases of aortic insufficiency showed a Flint murmur.

As to the character of the diagnostic features, certain clinical differences were found between the Flint murmur cases and those complicated with mitral stenosis. The Flint murmur is never as rasping and intense as that in stenosis; the presystolic thrill is less frequent, less intense, and in but few instances does the apex impulse have the tapping character so significant of true mitral stenosis; the snapping valvular first sound is also rare; the absence of history of acute infectious processes is also of assistance in making the distinction.

DR. CABOT said that a review of the post-mortem records at the Massachusetts Hospital had confirmed in detail practically all that Dr. Thayer had said. In the last 100 cases of aortic regurgi-

tation, which he had examined in the same way that Dr. Thayer did, he had found the Flint murmur in something over 50 of them.

Dr. Alfred Stengel, of Philadelphia, read a paper on

THE CAUSES AND CLINICAL FEATURES OF CARDIAC HYDROTHORAX.

He referred to the cases of unilateral pleural dropsy reported by Steele, which he had observed with the latter, and called attention to the fact that most writers have stated that effusion in heart disease is always bilateral. He had frequently found it unilateral, and when single it was always right sided. He analyzed 100 consecutive cases of cardiac disease that had been under his observation, and in which sufficient clinical and pathological information was preserved to make the notes valuable. Of these 17 showed evidences of hydrothorax, of which 5 were right sided only, 3 left sided, but in 2 of these the right pleura was found at autopsy obliterated. Nine had bilateral effusion at some stage; 2 of these were first right sided and then double, and in the other 7 the right side was more affected than the left. He said it was sometimes difficult to determine whether an effusion was dropsical or inflammatory, but the former could occur unilaterally.

He considered at some length the anatomical conditions that might permit or cause a one-sided effusion through obstruction to the circulation, and found support for the clinical evidence that the chances for such an effusion to occur are better on the right than on the left side.

Dr. Osler thought the history of these cases pointed to a local cause, and said that the three interesting points about all of them were: (1) The extraordinary chronicity of the cases; (2) the sudden onset of the hydrothorax; and (3) the almost invariable fact that these cases are mitral and the right side is chiefly involved.

Dr. Wilson thought that the mechanical conditions should be taken into consideration in explaining the disparity in the amount of fluid on the two sides. Referring to the two pleural cavities as closed sacs, and the right one being occupied by compressible lung tissue, he found the left to contain such tissue, but to be occupied also to a large extent by an enlarged incompressible heart, which would prevent the rapid transudation of fluid on that side.

Dr. Hare considered the movements of the heart to be another important factor, and believed it possible that the diastole and systole of the heart might urge on the fluids on that side without influencing the other.

Dr. A. Jacobi, of New York, presented a paper entitled

(To be continued.)

Plague in South Africa.—The total number of plague cases reported up to May 28 has been 651, and the deaths from the disease 300. Rats at Port Elizabeth are still said to be dying of plague. The conditions on the whole, however, are improving.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 30, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

SOME RELATIONS OF MEDICINE AND SURGERY.

There is little reason to doubt that what we now broadly speak of as medicine and surgery will, as time goes on, show an increasing tendency to invade each other's domain. In fact, apart from mere operative technique, very many surgical problems are primarily medical, and certainly many medical problems become surgical as the underlying disease progresses. The generally recognized separation of medicine and surgery depends finally upon the comparatively superficial basis of operative skill, the whole field of diagnosis occupying a common ground. However keen the surgeon's desire may be to accomplish definite results through operative means, the fact remains that by far the larger portion of his professional work is taken up with a consideration of the primarily important matter of diagnosis, of the determination of the advisability of operation — a strictly medical matter. The ease with which operations may now be performed has in the past and will, no doubt, in the future, lead, on the part of certain men, to a lack of discrimination in determining as exactly possible the underlying condition for which the operation is undertaken. We still hear much, though possibly less than formerly, of exploratory operations, justified unquestionably in certain cases, but bad in principle, if there is the slightest opportunity of determining pre-existent conditions. What we look for now in the really successful surgeon is discrimination, another word for conservatism, and fortunately this tendency is everywhere visible. With modern methods, courage more often lies in refraining from operation than in operating. In general, we see about us a growth of the tendency to look more broadly and deeply at medical matters, to use our reasons more and our impulses less; and this applies peculiarly to sur-

gical procedures. The medical side of surgery, diagnosis, pathological anatomy and the causes of disease, are coming to occupy their proper place. This clearly is a necessity if surgery is to keep pace with the scientific tendencies of medical knowledge in general.

As a type of the failure to clearly recognize the interrelation of medical diagnosis and surgical interference, there is probably no better example than operations on the spine for traumatic injuries of the cord. In this matter, on the part of certain writers, there is a persistent disregard of the palpable fact that the question at issue is almost invariably a medical one, and only secondarily surgical. The essential matter to determine is, how much the cord is injured, rather than whether or not laminectomy may be safely undertaken. And yet we see, from time to time, papers appearing with reports of cases in which no discussion of the medical side of the question is made, or of the pathological anatomy of the condition, or of the possibility of improvement without operation. For example: At the recent meeting of the American Surgical Association, Dr. Stephen H. Weeks read a paper on "Fractures and Dislocations of the Spine," in the course of which he said: "I believe the surgeon should perform laminectomy in every case, if the condition of the patient is such as to justify any operation, regarding the operation in the first instance as an exploratory one." Following this are various details regarding the dangers of the operation, and a warning that every precaution must be taken to avoid the attending shock. Unlike others, Dr. Weeks admits the gravity of the operation in itself, and yet without further statements regarding the medical side of the question, advises an exploratory operation in all cases, provided the condition of the patient is such as to justify any interference. What we object to, is the lack of discrimination, arising, we are forced to believe, from a too strictly operative point of view. Nothing is more firmly established than that a crushed or injured cord does not recover. If operation is to be attempted at all, it should only be after a most careful study of the symptoms of each individual case, remembering, too, that many cases reported as improved after operation might have improved without interference.

The only point, however, which we wish to make here, is that general statements regarding serious operations are out of place, and not in accord with the spirit of modern surgery, unless accompanied by the medical bearings of the subject under discussion. Laminectomy, as a procedure in operative surgery, is no doubt indicated in a limited number of cases, but even then its justification depends wholly upon other considerations than comparative operative safety. In general, it is certainly safe to say, as we implied at the outset, that the surgeon of the future must devote an increasing share of attention to the conditions which underlie surgical complications. By this means, no doubt, some of the artificial barriers between two subjects, which are in reality one, may in time be broken down, to the decided advantage of medicine at large.

A HOSPITAL CORPS GRADUATION AT MANILA.

A RECENT graduation of nineteen men of the so-called Company of Instruction from one of the Reserve Hospitals at Manila was made an occasion of considerable dignity by the presence of the commanding general and chief surgeon of the division. The object of the affair was to lay more stress upon the importance of this arm of the service than is ordinarily done. Various men, prominent in the army, spoke, describing the work of the Hospital Corps, and its possibilities for the future. General McArthur addressed the graduating class, and presented each member with his diploma. Colonel Greenleaf gave an interesting sketch of the development of the Hospital Corps from the Civil War down to the present. The remarks of the valedictorian of the class, Homer C. Lawson, were received with much enthusiam. Among other things he said: "In no department of the United States Army is there as much responsibility resting upon an individual as there is upon the soldier of the Hospital Corps. Upon his prompt action and coolness in danger often depend the lives of his comrades. How many soldiers, wounded in battle and far from medical assistance, are saved by first aid treatment? And in the time of trying need, when a whole army may be threatened by the invasion of disease, how often is the danger averted by the timely and discreet action of the sanitary soldier. In the very beginning, I wish to emphasize and impress the fact that above all things a Corps man is a soldier. What constitutes a soldier in the true sense of the term? All honor to our comrades behind the gun, but it does not necessarily follow that he alone is a soldier, or that bravery and loyalty cannot be shown in an equally effectual though different manner. We wish to prove that a trained Corps man is of equal value with his brother of the line in battle, in camp or in garrison. In the field a Corps man faces every danger that is encountered and risks his life equally as often as the man behind the gun."

These are simple enough facts, told in a simple way, and we hope that their reiteration will do something toward the better recognition of the

medical service in all its departments. In general, it must be taken as a good sign that these graduating exercises were given an importance usually not accorded to them, due mainly to the efforts of the commanding officers, Major Kulp and Lieutenant Lyster.

BOSTON'S ICE.

It is unfortunate for our complete peace of mind that, year by year, new menaces to health arise. A recent addition to the list is the quality of the water supplies from which our ice is obtained. It is self-evident that the sources of contamination increase in proportion to the growth of population in the neighborhood of ponds from which ice is cut. Not long since, Alderman Norris, of the city government, advocated the appointment of a chemist to investigate the ice sold in Boston, with relation to impurities of various sorts inimical to health. It appears that about a year ago Dr. Hill of the Bacteriological Laboratory, at the instigation of the Board of Health, studied the whole subject, as a result of which certain regulations were adopted, which dealers in ice were expected to obey. Were these regulations carried out, which demanded exact information from the dealers regarding the source, character and means of transportation of their ice, there is small reason to fear the origin or spread of disease from this cause, inasmuch as it is perfectly well known to the Board of Health that certain ponds, through proximity to sources of pollution, are unsafe. It is also clear that with the still greater growth of the city and its environs, the disposal of sewage will be more adequately provided for, thereby decreasing materially what now in certain instances might be a positive source of danger.

MEDICAL NOTES.

An Example of Newspaper Surgery.— The following paragraph, reported apparently in good faith by a daily contemporary, is not likely to spread accurate medical knowledge, however much it may redound to the credit of surgery in the popular mind. "Perry Taylor is one of the few human beings from whom doctors have successfully removed an entire lung. The patient, who is twenty-six years of age, was stricken about four years ago with what he believed was galloping consumption and was treated accordingly by the physicians consulted. Fully 240 cysts were removed in one operation, and then it was decided that the whole lung would have to come out. The operation was successfully performed. Taylor seems to have recovered his strength and is in the best of spirits."

Death of Marie J. Mergler, M.D.— The death of Dr. Marie J. Mergler, of Chicago, is announced from California, where she had gone for her health. She was one of Chicago's most prominent women physicians and held during her life many positions of trust and responsibility connected with her profession.

Testimonial to G. Armauer Hansen.— It is proposed to honor Dr. G. Armauer Hansen, of Bergen, distinguished for his services in the scientific study of leprosy, by a bust, for which contributions are sought from various countries. Subscriptions ranging from $2.50 to $5.00 may be sent to Dr. Sandberg, Bergen, Norway.

Diphtheria Not Subject to Quarantine.— The steamer "Rhynland," which arrived at Philadelphia May 12th with three cases of diphtheria on board, was, according to the *Medical News*, passed by both Federal and State quarantines. A list of the passengers who were to stop in Philadelphia was furnished the Board of Health, and the three persons afflicted were removed to the municipal hospital.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, May 28, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 77, scarlatina 24, measles 204, typhoid fever 8, smallpox 4.

Boston Mortality Statistics. — The number of deaths reported to the Board of Health for the week ending May 25th was 213, as against 200 the corresponding week last year, showing an increase of 13 deaths, and making the death rate for the week 19.8. The deaths from consumption were 24, pneumonia 18, whooping cough 1, heart disease 15, bronchitis 10, marasmus 4. There were 12 deaths from violent causes. The number of children who died under one year was 36, under five years 54, persons more than sixty years 50; deaths in public institutions, 53.

Hospital not Liable for Alleged Injury to Patient.— The United States Circuit Court of Appeals has affirmed the judgment of the Circuit Court which was for the defendant in the case of a patient against the Massachusetts Homeopathic Hospital. This was a suit brought to recover damages for an injury alleged to have been sustained by the negligence of a nurse in the hospital in the use of a hot-water bottle. The plaintiff was at the time paying for her care, a fact which her counsel attempted to make use of. The court ruled: "Commonly, and in the case at bar quite manifestly, this payment does not make full pecuniary compensation for the services rendered.

The pay is generally calculated upon the patient's ability to pay rather than upon the whole cost of the treatment he receives. That such a hospital in its treatment of a rich patient shall be held to a greater degree of care than in its treatment of a pauper is not to be tolerated."

SMALLPOX AT MARLBORO AND DEDHAM, MASS.— The first case of smallpox for eight years in the town of Marlboro has recently been reported to the Board of Health. It is reported that a case of smallpox has appeared in Dedham, Mass., said to be the first for fifty years. The patient is a young woman who had been employed in Boston.

NEW YORK.

CONVICTION OF A FOLLOWER OF DOWIE.— J. Luther Pierson, a resident of Valhalla, a nearby village, has been convicted in the Westchester County Court, at White Plains, of violation of Section 288 of the Penal Code in neglecting to provide medical attendance for a child, two years old, which died recently from pneumonia. The offense is characterized in the law as a misdemeanor, and the sentence of the court was that he should pay a fine of $500, and, failing to do this, to stand committed to the county jail for one day for each dollar of the fine. Pierson, who is a member of the "Christian Catholic Church, of Chicago" (or follower of Dowie), stated during the trial that while he admitted the existence of disease, he believed that it came from the devil, and could be cured only by prayer and faith, without the use of material agencies.

LIBRARY OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS, NEW YORK.— The Library of the Medical Society of the County of Kings was founded in 1845. On May 19, 1900, the library of over 30,000 volumes, 15,000 pamphlets, and some 500 current medical periodicals was thrown open free to the public. In addition to the very latest publications, the collection is especially rich in classics. The earliest printed volume is a folio published A.D. 1474. The first donation to the permanent invested endowment was the "Dr. John Lloyd Zabriskie Memorial Library Fund," presented in 1899 by Mrs. Zabriskie as a memorial of her husband, the late Dr. John Lloyd Zabriskie.

CARELESSNESS IN GUARDING AGAINST SPREAD OF SMALLPOX.— Recently a trained nurse who was taken ill, after having been in attendance on a patient who proved to have smallpox, was admitted to Harlem Hospital, and, with an extraordinary lack of precaution, was placed in a ward with sixteen other patients. When she herself developed the disease there was consternation in the institution. The patient was removed to the Willard Parker Hospital, the ward was placed in quarantine, and the Medical Board ordered the vacinnation, for the seventh time during the present season, of the entire medical and nursing staff of the hospital.

Miscellany.

THE ADIRONDACK COTTAGE SANITARIUM.

IN the sixteenth annual report of the Adirondack Cottage Sanitarium, for the year 1900, the president and physician in charge, Dr. E. L. Trudeau, states that the accommodations at the infirmary, which has only six beds, are now at times entirely inadequate, and a new and larger infirmary building is greatly needed for the proper care of the more acutely ill patients. The rapidly growing recognition by the public and the profession, of the value of sanitarium methods wherever they have been adopted, is shown by the fact that applications for admission to the institution from Massachusetts — the first and as yet the only State in which a State Sanitarium for Consumptives exists — have more than doubled since the adoption of this method of treatment there under State control. The number of patients admitted from the different States during the past year was as follows: New York, 136; Massachusetts, 22; New Jersey, 18; Canada, 18; Maryland, 14; Connecticut, 9; Ohio, 8; Pennsylvania, 8; Vermont, 5; Virginia, 5; District of Columbia, 4; Rhode Island, 4; Maine, 3; Michigan, 2, Missouri, 1; Illinois, 1; Iowa, 1; Kentucky, 1; England, 1; Germany, 1.

The work done by the sanitarium during the past year may, therefore, be summed up briefly as follows: 262 patients have been treated. To 224 of these the institution has furnished the best possible means of restoration to health at a nominal price, and to 38 entirely free of cost to them.

Correspondence.

SALSOMAGGIORE (PARMA).

GRAND HOTEL DES THERMES,
May 14, 1901.

MR. EDITOR: — Italy has numerous spas of various kinds, but lack of enterprise has thus far prevented their merits becoming known to medical men of other nationalities. The best of them, so far as the natural properties of its waters are concerned, is Salsomaggiore, a little place of 1,500 inhabitants in the Province of Parma. It is a quaint and rather picturesque village, connected by a steam tramway with Borgo San Domino, which is a station on the main line between Rome and Milan (via Florence); so that there is nothing left to desire in the way of accessibility. It can be easily reached in thirty hours from either London or Paris, and for Americans who land at Genoa it is no more than a half day's easy journey.

For many centuries the waters have been used for the manufacture of salt, and it was not until 1839 that Berzieri, the village doctor, tested their effects in cases of syphilis and scrofula. His successor continued these researches and went so far as to build a couple of baths in his own house for the treatment of his patients.

From these small beginnings have sprung into existence three large and well-installed *stabilimenti*, each with its own well driven to a depth varying from 400 to 700 mètres. The waters are used in every possible way for the treatment of all diseases where resolution and absorption are the potent factors in obtaining a cure; immersion, inhalation, douches, and every conceivable form of outward and inward use aside from drinking, for which the water is unsuitable, as shown by the analysis, which proves each kilogramme to contain the following number of grammes: Sodium, 153.990; lithium, .735; ammonium, .637; calcium, 15.848; strontium, .255; magnesium, 5.584; iron, .033; aluminum, .059; manganese, .005; magnesium bromide, .303; magnesium iodide, .006; magnesium borat, .011; ferrum bicarbonate, .077; strontium sulphate, .603. The natural temperature is 14° C. (57°+F.) and the density 15°—16° Baumé. The water, as discharged in intermittent jets from the wells, is clear, but quickly turns brown from oxidation, and leaves a deposit on the sides of the tanks and pipes. Before it is allowed to reach the enormous receptacles used for its storage, it undergoes a straining process, and the mud thus extracted is employed in the way of ordinary "fango" baths. It differs, however, in color from the usual "fango" so much used at Dax and throughout Germany, and is strongly impregnated with the salts which the water contains. After reaching the tanks a thick scum of greenish-black petroleum quickly appears on the surface of the water, and this is skimmed off and subsequently refined. There is also a large amount of natural gas discharged from the wells, which is stored and used for heating and lighting purposes. Nature's laboratory certainly appears to turn out a varied assortment in this instance.

As a by-product, resulting from the extraction of chloride of sodium by evaporation, comes the *acqua madre* ("mother water") in which, of course, the percentage of the other salts is enormously increased. This condensation, modified in various degrees, is used for inhalation, and has proved very effective in cases of chronic laryngeal and bronchial affections, as well as in obtaining very rapid absorption of iodine, etc., as is easily proved by examining the urine after a single treatment. One may take the inhalations by direct atomization (Pierry's) or by the Jannigen and Beiselen's method, breathing the air of a large room which is filled with a white mist of the finely pulverized water. I have personally known of a case of most troublesome cough from which an old gentleman had suffered for fifteen years, where almost complete relief was obtained after a few days' treatment.

As ordinarily employed, the "cure" consists of twenty-one baths of the natural water from which the "fango" and petroleum have been removed. At the commencement of the treatment the specific gravity is 4% Baumé, and this is gradually increased to 9° or at the most 12°. At the last named density the patient is as "helpless as a jellyfish," and special measures are necessary to prevent his "floating like a toy duck."

The source of the drinking water supply is above suspicion and the village is clean and orderly. The people of the place, whether employés of the baths or not, seem to be a quiet and civil lot, among whom beggars are very rare. The village lies in a pretty little valley at the foot of the Appenines, at an elevation of a little over 500 feet above the sea and surrounded by rather low cultivated hills on which are vineyards, gardens and occasional olive groves. Aside from excursions to three or four ruined castles (Bargone, Vigoleno, etc.), there is but little to do in the way of amusement in the near neighborhood; but fortunately it is a short ride to Parma by rail and but little more than a couple of hours to Milan; so that a fairly able-bodied invalid can easily find entertainment on such "off days" as his cure may permit.

This year a small theatre, or rather *café chantant* has been opened, and light operas (chorus particularly robust) are given every evening. Shops of the better kind are beginning to appear, and as the place attracts the notice which it certainly deserves, all the usual accompaniments of a fashionable spa will follow.

The baths and inhalations are remarkably well done, and everything about the *stabilimenti* is bright and clean. Disinfectants are regularly employed to insure safety; and there is no lack of system (so painfully in evidence at many other places) in carrying out the treatment.

Of the three establishments, the Therme Magnaghi is the newest; but the pleasantest way to take the "cure" is to live at the new Hotel des Thermes in which the water is brought directly from the well onto each floor, and one has but to walk along the corridor to find clean bath rooms and good attendance.

To those who have been jolted about in *chaises à porteurs* after a hot douche in other continental resorts, this will prove a grateful change.

Another advantage of Salsomaggiore is the reasonable rate at which one may live while taking the baths.

So far as medical attendance is concerned, aside from the regularly salaried physicians at the establishments there are Dr. Ceccherelli, professor of clinical surgery in the University of Parma (who has been in the habit of sending patients to Salsomaggiore for many years, and has written a number of neonographs on the therapeutic properties of the waters) and Dr. J. J. Eyre who practices in Rome in winter and is the translator of Celli's book on malaria and Montis (prize) essay on pathology.

The list of diseases in which the waters have achieved good results includes scrofula and other forms of tuberculosis, rickets, chronic affections of the larynx and bronchi, chronic gout and rheumatism, chronic rheumatoid arthritis, pelvic troubles in women and syphilis.

To what extent the salts are absorbed *by the skin* remains an open question; but it certainly seems that a spa whose waters contain something more than a stench of sulphuretted hydrogen and table salt is worthy of the notice of the profession. Such rheumatic cases as I have had an opportunity of observing, have certainly improved after the first ten baths, and the quick relief afforded in two cases of asthma within my personal knowledge, have impressed me with the efficacy of the inhalations. In summer the hotels are crowded with Italians, and the weather is too hot for comfort; but May, early June, September and October are all pleasant and the rainfall usually slight. The place is healthy, and is destined to prove a powerful rival to the best known baths in Europe within the next few years.

Very truly yours,

F. GORDON MORRILL, M.D.

METEOROLOGICAL RECORD.

For the week ending May 18th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,120; under five years of age 679; principal infectious diseases (smallpox, measles, scarlet fever, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 500, acute lung diseases 277, consumption 231, scarlet fever 70, influenza 2, erysipelas 6, typhoid fever 16, whooping cough 13, measles 13, cerebro-spinal meningitis 14, smallpox 13.

From whooping cough, New York 2, Pittsburg 10, Cambridge 1. From cerebro-spinal meningitis, New York 3, Baltimore 1, Pittsburg 4, Lynn 3, Boston, Brockton and Haverhill 1 each. From scarlet fever, New York 59, Pittsburg 2, Providence 1, Boston 7, Cambridge 1. From typhoid fever, New York 4, Baltimore 2, Pittsburg 5, Boston 2, Worcester, New Bedford and Weymouth 1 each. From erysipelas, New York 5, Baltimore 1. From smallpox, New York 13.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,789,099, for the week ending May 4th, the death rate was 17.3. Deaths reported, 3,799; acute diseases of the respiratory organs (London), 251, whooping cough 133, diphtheria 55, measles 107, fever 20, scarlet fever 34.

The death rate ranged from 9.7, in Croydon to 26.5, in Swansea; Birkenhead 15.9, Birmingham 18.0, Blackburn 20.0, Bolton 21.6, Bradford 15.6, Brighton 14.3, Bristol 15.2, Burnley 16.1, Cardiff 13.9, Derby 17.2, Gateshead 24.1, Halifax 18.8, Huddersfield 15.9, Hull 18.5, Leeds 18.0, Leicester 11.5, Liverpool 20.7, London 16.7, Manchester, 18.5, Newcastle-on-Tyne 18.9, Norwich 16.3, Nottingham 19.3, Oldham 15.6, Plymouth 14.5, Portsmouth 16.7, Preston 18.5, Salford 20.5, Sheffield 18.6, Sunderland 21.3, West Ham 13.2, Wolverhampton 12.7.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, WEEK ENDED MAY 18, 1901.

J. C. WISE, medical director, appointed member of Examining Board, Annapolis, Md., for examination of candidates for cadets.

W. B. GROVE, passed assistant surgeon, orders as member of Examining Board, Naval Academy, revoked.

C. BIDDLE, surgeon, detached from navy yard, Philadelphia, and ordered to the Indiana.

O. DIEHL, surgeon, detached from the Indiana, and ordered to the Philadelphia Navy Yard.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED MAY 23, 1901.

PECKHAM, C. T., surgeon. Granted leave of absence for thirty days from April 19th on account of sickness. May 16, 1901. Granted thirty days' extension of leave of absence on account of sickness from May 20. May 21, 1901.

GLENNAN, A. H., surgeon. To rejoin station at Habana. May 21, 1901.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Meridian, Miss., for special temporary duty. May 18, 1901.

GREENE, J. B., passed assistant surgeon. Granted five days' extension of leave of absence. May 19, 1901.

DECKER, C. E., assistant surgeon. Granted leave of absence for ten days from May 11th, on account of sickness. May 20, 1901.

CLARK, TALIAFERRO, assistant surgeon. Granted leave of absence for thirty days from May 22d. May 22, 1901.

CORPUT, G. M., assistant surgeon. To proceed to South Atlantic quarantine. May 16, 1901. Granted leave of absence for one month. May 16, 1901.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for four days. May 18, 1901.

SLAUGHTER, A. W., acting assistant surgeon. Granted leave of absence for four days from June 4. May 22, 1901.

BOARD CONVENED.

Board convened to meet at Washington, D. C., May 20, 1901, for the purpose of making physical examination of applicants for cadetship in the Revenue Cutter Service. Detail for the Board: Surgeon L. L. Williams, chairman; Assistant Surgeon B. S. Warren, recorder.

SOCIETY NOTICES.

MAINE MEDICAL ASSOCIATION. — The forty-ninth annual meeting of the Maine Medical Association will be held in Portland, Me., Wednesday, Thursday and Friday, June 12, 13 and 14, 1901.

ROENTGEN SOCIETY OF THE UNITED STATES. — The second regular meeting of the Roentgen Society of the United States will be held in Buffalo, N. Y., at the University of Buffalo, September 10 and 11, 1901.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. — The fifty-seventh annual meeting of the American Medico-Psychological Association will be held at Milwaukee, Wis., June 11, 12, 13 and 14, 1901. There will be reduced railroad rates as far as St. Paul.

RECENT DEATHS.

GEORGE STONE OSBORNE, M.D., M.M.S.S., died in Salem, May 25, 1901, aged sixty-two years.

ALLEN MELANCHTHON SUMNER, M.D., M.M.S.S., died in Boston, May 25, 1901, aged fifty-seven years.

THOMAS ALBERT O'CALLAGHAN, M.D., M.M.S.S., died in Worcester, April 13, 1901, aged forty-six years.

EPHRAIM LEWIS WARREN, M.D., M.M.S.S., died in Melrose, April 28, 1901, aged seventy-eight years.

HARRIS ORLANDO PALMER, M.D., M.M.S.S., died in Hubbardston, February 17, 1901, aged fifty-nine years.

DR. JOHN A. WELLS, a prominent physician of Englewood, N. J., died from pneumonia on May 21st, at the age of forty-five.

DR. HENRY D. WHITBECK, who had practiced for nearly forty years in Syracuse, N. Y., died in the hospital of the Soldiers' Home at Bath on May 21st. During the Civil War he served in the 98th Regiment, New York Infantry.

DR. CONRAD WEINGES, of Jersey City, N. J., died on May 23d, at the age of fifty-two, from multiple neuritis. He was a native of Charleston, S. C., and was educated at Carroll University. He was graduated from the College of Physicians and Surgeons, New York, in 1883.

BOOKS AND PAMPHLETS RECEIVED.

A Treatise on Orthopedic Surgery. By Royal Whitman, M.D. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1901.

Address.

THE VALUE OF CLINICAL MICROSCOPY, BACTERIOLOGY AND CHEMISTRY IN SURGICAL PRACTICE.[1]

BY JOHN M. WYETH, M.D., NEW YORK.

For many years, almost without exception, my predecessors in the address on surgery have devoted their labors to the exposition of some general or special subject in the domain of operative surgery, and while I would in no measure detract from the value of a thorough technical knowledge, we should not, in our attention to the *art*, fall short of a proper appreciation of the *science* of surgery.

The experienced surgeon soon learns that it requires more than asepsis and the rapid and skilful performance of an operation to achieve the fullest measure of success; that, although a thorough practical knowledge of regional anatomy is essential in the highest degree to the conscientious fulfilment of the professional obligation, it is equally important that there be called into requisition the invaluable aid which laboratory research alone can give in determining an accurate diagnosis; in indicating the most rational measures of treatment not only in the preparation of a patient for an operation, and in the selection of the safest anesthetic, but for the post-operative management of the case, and in removing as far as possible all doubts as to the prognosis.

Chemical analysis of the normal and abnormal secretions and excretions of the body, *clinical microscopy* and *bacteriology* should form a part of the educational requirement of every surgeon. I do not insist that the busy practitioner should attempt to master all the intricate processes of the laboratory, for this is only possible to one who devotes years of patient labor in the fascinating department of science, but he should possess that practical knowledge of the chemistry of the body in health and disease, and of clinical microscopy and bacteriology which any diligent student, under a competent teacher, and in a properly equipped laboratory, should be able to acquire in a three months' course of study.

The instances are exceptional in practice where this knowledge cannot be applied with great benefit to the patient and with satisfaction to the surgeon. It is naturally of greatest value in the cases where no emergency for immediate operation exists; but its advantages are not wanting in these rarer cases, since it comes to his aid in the post-operative period.

Laboratory research, especially in the department of bacteriology, has placed not only the medical profession, but the entire human family under lasting obligations for the great benefits which have already been derived from its discoveries, and it may be safely said that it has done more than all else in accomplishing the revolution in surgical thought and practice which has taken place within the last two decades. One of the most notable illustrations of this great advance is the triumph which has been achieved over that once fatal disease, diphtheria.

The discovery by Klebs, in 1883, and the isolation and cultivation, in 1884, by Loeffler of the bacillus of diphtheria, had its logical sequence in Behring's invaluable discovery (subsequently elaborated by Roux) that the blood of animals, especially that of the horse, rendered immune to diphtheria by inoculation, first with attenuated, and then with more virulent organisms, contained a substance capable of neutralizing the effects of the bacilli or their *toxin* when simultaneously or subsequently inoculated in non-protected animals.

This antitoxin serum in its dose of 10 cc. of either the 600, 1,000 or 1,500 *immunizing units* is potent not only to arrest the destructive processes which formerly characterized this disease, but to prevent the infection of those who have been exposed to the contagion. How great is the importance of the knowledge that these bacilli are not only always present in the throat of a patient suffering from diphtheria, but that they are frequently found on the nasopharyngeal surfaces and tonsils of persons free from systemic infection, and as shown by Biggs, Parke and Beebe, of New York, they may remain as long as five weeks after the membrane has been discharged from infected subjects, all of which points to the necessity for the isolation of the infected individual, and the careful disinfection of the throats of those who have been about diphtheria cases. (McFarland.)

The statistics of Professor Welch, of Johns Hopkins University, show that the ratio of mortality as a result of these discoveries has been reduced more than 55%, and that in 115 cases, in which by reason of an early diagnosis, the treatment of serum antitoxin was begun within the first three days of the disease, the mortality was only 8.5%. In 546 cases, in which the remedy was begun after the third day of the disease, the mortality was 27.8%, the ratio of mortality increasing with fatal precision as treatment was delayed.

To the surgeon, one of the most gratifying results of this great triumph of the laboratory is the fact that he is now rarely called upon to perform the operation of tracheotomy which was formerly distressingly frequent; nor to witness the sufferings associated with intubation of the larynx. A professional friend in the department of diseases of children informed me recently that, whereas a few years ago he had from 10 to 20 intubations of the larynx on account of diphtheria in every month, he now, since the serum therapy was practised, averaged only 1 or 2.

I believe that what is true of this disease is true of all infectious processes, and that as our knowledge expands, a safe immunizing serum will be discovered for each special toxemia. Even now it would seem that this proposition is proved in other infections in which, like diphtheria in patho-

[1] Oration on Surgery before the Fifty-Second Annual Meeting of the American Medical Association at St. Paul, Minn., June 4-7, 1901.

genic organisms, are localized at the seat of infection, their toxic products alone entering the tissues through the circulation.

Of this type is the spirillum or "comma" bacillus, discovered by Koch in 1884 in the intestinal contents of patients suffering from Asiatic cholèra. These germs are not found in the deeper organs, the morbid changes in the tissues being due to their toxin. Immunizing injections of cholera cultures have already been experimentally and successfully employed, and promise rich results.

In this same group, bacteriologists claim a place for the diplococcus micrococcus lanceolatus of Frænkel, the *pneumococcus*. Sternberg and Pasteur isolated this germ in 1880, and in 1884 Frænkel demonstrated it as the prevailing organism found in the sputum of croupous pneumonia. Very late investigations give encouragement to the hope that serum therapy will soon be applied in the early arrest of the invasion of this most painful and fatal malady. Though pneumonia is strictly a medical disease, its early recognition as a surgical complication, or in view of an anticipated operation, is of very great importance. In a recent case which came under my observation at our laboratory, a specimen of sputum was sent in for bacteriological study. It was not blood-stained or "brick-dust," but yellowish-white in color, like the ordinary sputum of bronchitis, and was supposed to be "grippe," or tuberculosis. The bacillus of tuberculosis was not present, but numerous micrococci lanceolati were discovered, and the laboratory diagnosis was made and confirmed within twenty-four hours by the well-recognized symptoms of consolidation with the "brick-dust" expectoration of this disease which supervened.

Tetanus toxemia, or "lock-jaw," the organism producing which was discovered by Nicolaier in 1894, and which for years has baffled the most strenuous efforts of the bacteriologist and clinician, seems at last to be classified with the controlable infections. Professor Osler, in the last edition of his "Practice of Medicine," says the immunizing serum of Tizzoni has been successfully and encouragingly employed in doses of 2.25 gms. for the first dose, and .6 gms. for subsequent doses. Of 113 cases treated by this method, 63% recovered.

It was not until the discovery of the bacillus of typhoid by Eberth in 1880, and the pure cultures of this germ secured by Gaffky in 1884, that there was made possible in the vast majority of cases of typhoid fever a positive diagnosis.

The demonstration of Widal that when 10 drops of a twenty-four hour bouillon culture of the bacilli typhi were added and thoroughly mixed with 1 or 2 drops of serum from the blood of a typhoid patient, the bacilli lose their motility and become agglutinated in masses, was one of the most brilliant advances in clinical bacteriology, and of great value in surgical diagnosis.

In many of the lesions of the abdominal viscera, and especially in those located in that battle ground of surgery, the right iliac fossa, where the physical signs and the febrile movement may suggest either beginning typhoid, intestinal toxemia or a pyogenic sepsis, an early diagnosis may be determined in no other way than by the aid of the laboratory.

The practitioner who has not called into requisition the invaluable aid which bacteriology affords in the differentiation of those too often obscure intraperitoneal lesions, can not appreciate the satisfaction which this practical application affords. How often the safety of a patient hangs upon even a few hours' time, and, alas, how often this precious time is wasted in the uncertainties of diagnosis, when a resort to the demonstration of science, available to all, would have plainly indicated the proper method of procedure. We know too well the fallacy of relying upon the ordinary subjective symptoms, and even some of the objective symptoms afford us no accurate clue to the pathological process which may exist. The pulse and the temperature of commencing typhoid may well be mistaken for the pulse and the temperature of an appendicitis. The pain and muscular resistance over the right iliac and the right abdominal region are in many instances practically alike. The nausea, the vomiting and the general sense of uneasiness point neither directly to the one or to the other disease, but in a crucial test by Widal's reaction, with the blood count pointing to the presence or absence of a leucocytosis, the question is quickly settled. I have seen all the symptoms of appendicitis present in cases in which the blood count contradicted a pyogenic sepsis, and in which Widal's reaction told the story of typhoid. On the contrary, I have dealt with cases which ordinarily would have been most perplexing, in which all the symptoms of typhoid prevailed at a period when it was too early to recognize this disease by Widal's test, and a leucocytosis of from 15,000 to 21,000 proved at the earliest possible moment that the case was one for immediate operation.[2]

The discovery by Bollinger in 1877 made the diagnosis of that comparatively rare affection, acti-

[2] Two of the cases occurring in my own work within the last few months may emphasize the great value of this technique. A man of thirty was seized with quite severe pains which were confined to the region of the cecum and appendix. Upon palpation there was well-marked resistance in the muscles immediately over these organs which was not observed in any other part of the abdominal wall. He had vomited on one or two occasions, and the temperature ranged from 101° to 103° F. on the second day of this attack. The questions which were presented to the consultants were whether this temperature could be accounted for by intestinal toxemia, by appendicitis or incipient typhoid. Although it was too early in the history of a typhoid case to encourage the belief that Widal's reaction would be present, this was made, and with negative results. On the following day, the symptoms still pointing toward typhoid fever, a careful blood count was made and the leucocytes did not count over 7,000. Assured from this that no dangerous pyogenic process was present, the idea of operation, even exploratory, was abandoned until the examination might be repeated on the succeeding day. A second careful blood count showed no leucocytosis, and on the fourth day, although Widal's reaction was still absent, the case was declared to be typhoid, and the subsequent history proved the diagnosis to be correct, since a few days later the reaction of typhoid was present, and the patient went through the regular stages of this fever. In a second case, a male patient, forty-five years of age, there was a typical typhoid tongue, temperature ranged from 100° to 103.5° F., tenderness and muscular resistance in the right iliac fossa and loose discharges from the bowels not unlike those frequently met with in typhoid. Widal's reaction was tried with negative results on three successive days. The blood count on the fifth day showed the leucocytes numbering 21,000, justifying a diagnosis which excluded typhoid, and confirmed the suspicion of pyogenic sepsis.

nomycosis, clear. In examining the yellow granules and accompanying pus discharged from an infected area he recognized the ray fungus or actinomyces. More recent researches have shown this fungus to be composed of bacilli in various stages of development, some being spores and some more perfectly developed organisms.

In another fortunately rare disease, malignant pustule, caused by the lodgment in an abrasion of the bacillus anthracis, we are indebted to the laboratory for our knowledge of its etiology. The anthrax bacillus, discovered by Devaine in 1863, is not usually found in the blood except in the most malignant cases and in the last stages of fatal infection, but they can be demonstrated in the pustule of inoculation with the microscope or by cultures.

Roux and Chamberland, according to McFarland, have found that filtered cultures will produce immunity when properly introduced into animals, and we reasonably hope from these experiments that the serum treatment will before long be made applicable to infected human beings.

Another rare organism is the bacillus of malignant edema, which was discovered by Pasteur in 1875 and called by him *vibrion septique*. There are only 2 cases of this disease so far reported in man, and they were subjects of abnormally low resistance infected by the hypodermatic administration of a product of musk.

The bacillus pestis or bubonic plague organism was discovered in 1894 simultaneously by Yersin and Kitasato, in blood drawn from the finger tips of infected individuals, and in the broken-down lymph glands, and is described by Kitasato as greatly resembling the micro-organism of chicken cholera.

Bacteriological research has robbed the puerperal state of much of the anxiety and dread which formerly attended this ordeal, not only in preventing sepsis, but in recognizing the infections already established in time to prevent a general peritonitis or septicemia. The puerperal uterus of this organ, when the seat of non-puerperal endometritis, offers an ideal field for bacterial proliferation and invasion, since septic organisms entering the cavity may rapidly penetrate the endometrium and enter the lymph channels, whence they pass into the venous sinuses and lymphatics of the pelvis.

Prof. W. R. Pryor, in a paper read before the New York State Medical Association in 1900, says, "Puerperal sepsis, if not rapidly fatal, almost always produces lesions which seriously damage the pelvic organs or the viscera," and that "time is in this serious condition an important element." He recommends the early employment of the Döderlein tube, which, after sterilization, is passed into the uterus, being protected from contact until the fundus is reached. From the serum and débris thus obtained cultures are made, and the character of the operation — either curettage or hysterectomy — determined by the result of bacteriological investigation.

Not only does the laboratory come to our assistance in the diagnosis of certain obscure surgical lesions of the stomach, but it is still more valuable as an aid in arriving at the exact condition of the digestive functions of this organ, any derangement of which it is at times exceedingly important to correct in order to bring a patient into suitable condition to stand an operation. Thus it is important to determine in certain instances whether or not free hydrochloric acid exists in this organ; and while the total quantity poured into the stomach in the digestive process can not be accurately measured, clinical chemistry can closely estimate the total quantity found at a given moment during digestion. The acid-combining power of the proteids is known, and by certain tests it is feasible to estimate sufficiently close for a satisfactory diagnosis the quantity of hydrochloric acid secreted. The small quantity of hydrochloric acid which combines with ingested inorganic elements is lost to gastric digestion, serving as it does its function in this process in the intestines.

It is clear, as stated by Van Valzah and Nisbit, that the hydrochloric acid which combines with the proteids, and that which remains free, together roughly represent the activity of acid secretion. It is logical then to conclude that the quantity of dydrochloric acid loosely combined with albumin, together with the quantity remaining free in the contents withdrawn at the end of a particular time after eating a particular meal, is a practical and clinical measure of the secretive activity of the peptic glands, and of the digestive work of the stomach. All of this is made sufficiently exact for practical purposes by the laboratory method of analysis after the simple test breakfast of Ewald and Boas, or the more elaborate test meal as recommended by Germain-Sée.[3]

The presence of lactic acid in the stomach contents, as shown by Kelling's test,[4] has a distinct diagnostic value, since it takes place in comparatively rare conditions, and since these conditions

[3] The simplest method is that known as the test breakfast of Ewald and Boas in which on an empty stomach, usually in the early morning, a breakfast roll which contains about 5 gm. of proteids, 30 gm. of carbohydrates, 1-3 gm. of fat, 3-4 of a gm. of ash, and weighs 70 gm., and 300 cc. of water (about a glass and a half) are taken. The bread should be thoroughly chewed and insalivated before being swallowed with the water. Usually in one hour's time a tube is introduced and the contents of the stomach withdrawn, usually by expression or by siphonage, and then filtered. An estimate of the acidity of the filtered contents is made by using a deci normal solution of potash or soda. The number of cc. of this solution which will neutralize 100 cc. of the filtered contents of the stomach expresses in figures the acidity of the fluid withdrawn. At the end of an hour, under approximately normal conditions of digestion, the total acidity should be 50 to 60, the hydrochloric acid albumin 30 to 40, the free hydrochloric acid 10 to 20. Any departure from this rule shows the abnormal absence or excess of this important agent. The test meal of Germain-Sée is at times preferable, since it contains a larger quantity of proteids than the test breakfast of Ewald and Boas just given, but the method of procedure is practically the same. The presence of hydrochloric acid can be recognized by Gunzborg's reagent which is composed of: Phloroglucin, 2 gr.; vanillin, 1 gr.; alcohol (absolute), 30 gr. By spreading three or four drops of this reagent in a porcelain crucible, adding upon this the same quantity of the filtered contents, and slowly warming the crucible, after several seconds a red color appears, and at times the red crystals of free hydrochloric acid are seen. Or the simpler method of employing a filtered paper, which has been soaked in a .5% alcoholic solution of diamethylamidiazo-benzol and dried. This, in the presence of a trace of free hydrochloric acid, turns distinctly red.

[4] Kelling's test consists of 5 cc. of the filtrate diluted to 50 cc. with distilled water, to which one or two drops of official 9% solution of the perchlorid of iron are added. The yellowish-green tinge indicates the presence of lactic acid.

are seldom fulfilled except when carcinoma is present.

Lactic acid is dependent upon the presence of a special bacillus which thrives in the stomach under abnormal conditions, and is capable of converting glucose and lactose into lactic and carbonic acid. Boas goes so far as to insist that the persistent presence of lactic acid in noteworthy quantity during the digestion of a saucer of oatmeal, chemically free from lactic acid, is a specific sign of carcinoma of the stomach.

While the stomach may under varying conditions contain hosts of various bacteria in addition to the one just considered, there are only three others that are of importance as pathogenic organisms. First, the *sarcinæ ventriculi* (in their usual cube arrangement) which when found indicate insufficiency of the stomach muscle due to non-malignant obstruction. They are not found in carcinoma, since they perish in the presence of lactic acid, which, as we have just shown, is so common in malignant diseases of this organ. Another micro-organism is the *yeast plant*, also found when motor insufficiency exists. It may be present when the stomach contents are alkaline, neutral or acid. The *bacillus geniculatus* is present under the same conditions which produce the lactic acid organism, and is considered also to be suggestive of carcinoma.

When the presence of blood is suspected in the stomach, and is not clearly defined by the microscope, chemistry comes to our aid in its recognition by the glacial acetic acid and ether test.[5]

A study of the discharges from the rectum is as yet of little value to the surgeon. Beyond the recognition of blood or pus, or cast-off cell elements in certain malignant neoplasms, there is but a single organism which is of real diagnostic value, namely, the ameba of dysentery, described by Lamb in 1859, which is a motile mass of protoplasm about 20 mmm. in diameter, containing a single nucleus, and one or several vacuoles.

In the differentiation between the pathogenic organisms of specific and non-specific urethritis, microscopy and bacteriology are our only infallible guides. They teach us to eliminate the various bacteria found in the external genital and urinary passages, not bearing directly upon the etiology of urethritis, and to recognize distinctly the two forms of diplococcus, the gonococcus of Neisser, and the pseudodiplococcus, which, while not morphologically different from the specific disease-producing organism, can be readily distinguished by special modes of staining as well as by cultures. In the daily routine of practice the exact nature of every suspicious urethral discharge should be subjected to careful scrutiny. The patient is entitled to the satisfaction of a negative result, which is easily demonstrated by staining the smear with methylene blue, which clearly defines both organisms. If no cocci are revealed all anxiety is put at rest; but if there are present both varieties of these organisms, occupying as they do, the protoplasm of the pus corpuscles, a further research and the differentiation of the true form from the false diplococcus is imperative. The pseudococcus retains the violet color of the aniline-gentian water violet stain, while with careful laboratory technique the addition of the Bismarck brown brings out the gonococcus, the protoplasm of a single pus corpuscle showing at times both the blue stain of the pseudococcus and the diplococcus of Neisser which retains the brown color.[6]

Bearing in mind the fact that the gonococcus of Neisser may remain dormant in these passages for months, and, as maintained by some observers, for years, incapable of a further inoculation of the seemingly immunized patient, but capable of exciting the most acute and injurious inflammation in an innocent victim, it becomes a matter of the greatest importance to subject to most careful study the external genito-urinary passages where an infection has once existed. It has been demonstrated that an artificial urethritis, as that which nitrate of silver produces, will develop the dormant gonococci and cause their presence in the discharge.

Keys and Chetwood, in their excellent volume on venereal diseases, place well-deserved emphasis upon the value of the Gram test for recognizing these organisms. They properly insist that the diplococci should be of the recognized size, and have within the protoplasm of the pus corpuscle their proper shape and arrangement, and remain negative to Gram's staining. Even when cultures are made to demonstrate the specific organisms beyond all doubt, resort should still be had to the Gram staining as a final means of identification.

In cases of pyelitis, many of the difficulties which formerly stood in the way of differential diagnosis between renal calculi, simple pyogenic pyelitis or the presence of tubercular disease in this organ are now overcome by the careful methods of the laboratory.

The presence of the bacilli of tuberculosis in one or both kidneys, even when they are exceedingly infrequent in the discharge, can be demonstrated in urine drawn by urethral catheterization, or by the more simple process of bladder segregation, when the suspected organisms are with other detritus thrown down by the centrifuge. The carbol-fuchsin stain, decolorized with

[5] To 10 cc. of the filtered contents add 3 cc. of glacial acetic acid, and extract the coloring matter of the blood by shaking with 5 cc. of ether. This turns the ether extract brown. When this discoloration does not take place there is no blood. To carry the demonstration further, to the brownish decanted ether extract, 10 drops of fresh tincture of guiac with a few drops of peroxid of hydrogen are added. After vigorously shaking, the mixture becomes clear blue if blood is present.

[6] Dr. Jeffreys, the director of the laboratory in the New York Polyclinic, employs the following differential stain: Use Gram's stain followed by a contrast stain, such as Bismarck brown. To prepare this stain proceed as follows: Prepare aniline water by emulsifying 8 drops of aniline oil in about 10 cc. of water. Filter through a wet filter. To this aniline water, add about one-tenth its bulk of a saturated alcoholic solution of gentian violet. Stain smear with this "aniline water gentian violet" one or two minutes. Wash in warm water, and then immerse in Gram's solution for one minute. The formula for this solution is as follows: Iodin, 1 gm.; iodid of potash, 2 gm.; water, 300 cc. Thoroughly wash in 96% alcohol until no more blue appears to wash out; then wash in water. Counterstain for one minute with a saturated solution of Bismarck brown in 3% aqueous solution of carbolic acid. Wash, dry, and mount in balsam. After this treatment, pseudogonococci should be stained violet, and gonococci should be brown.

5% sulphuric acid, brings out in brilliant red the outlines of the bacilli of tuberculosis, while the addition of 95% alcohol decolorizes the smegma bacillus, and thus eliminates this possible source of error to any but the more expert laboratory workers.[1]

In the effort to arrive at the general condition of a patient, the chemical, microscopical and bacteriological study of the urine is only second in importance to that of the blood; and when we consider the additional and exact information which can thus be obtained concerning any pathological process at any point in the urinary tract, the value of this analysis is very materially increased. A careful study of the urine is always indicated before determining what anesthetic it is safest to employ in the operation to be undertaken. When there is no important lesion of the heart, either in its valvular mechanism or in the blood supply and nutrition of its muscular walls, few surgeons, I hold, would employ ether in a protracted operation in which there was any suggestion of an acute nephritis, or in certain chronic forms of Bright's disease.

It is commendable practice to study through several days the quantity of urine passed, keeping accurate measurement, as well as making a qualitative analysis of that which is passed under conditions as near as possible similar to those to which the patient had been subjected before coming under observation, and then under conditions of rest, with proper alimentation and the free opening of the alimentary canal with calomel and Carlsbad salts (which agents in my experience most readily do away with fermentation and the production of gases in the bowels) to note the changes which occur in excretion.

The presence of oxyluria is in my opinion a contra-indication to a serious surgical operation, for the reason that it is pathognomonic of a disturbed nutrition due to insufficiency of the digestive fluids, and to fermentative processes in the intestinal tract.

An excess of *uric acid*, evident in the rosettes or rhombic or quadrate crystals (one-sixth objective), found in the urine *which has not been passed* more than three or four hours, has also a pathological significance scarcely less than that of oxyluria. It indicates a condition of defective nutrition which is part of the gouty or rheumatic diathesis, predisposes to chronic nephritis, and is one of the symptoms of various acute inflammatory processes, of leukemia, cirrhosis of the liver, gastro-intestinal catarrh, and is often present in diabetes mellitus.

The chemistry and microscopy of the urine further informs us when ammoniacal decomposition of the urine is taking place within the bladder, suggesting insufficiency of this organ due to obstruction of the urethra or to atony of the bladder muscle. The large rhombic masses or stellate and cross-shaped rosettes of the triple phosphates only exist in these abnormal conditions of the bladder, and, with the brownish-colored, thorn-like crystals or urate of ammonia, are important aids to diagnosis.

The presence of epithelia from the various portions of the urinary or genito-urinary tract, of spermatozoa and various bacteria chiefly pyogenic in character, are further and well-recognized evidence of the value of the microscope in surgical diagnosis. In rarer instances, the hooklets of echinococcus, the embryos of filaria and the ova of hemotobium Bilharzii are thus discovered in the urine. The writer has been able once to demonstrate the presence of the eggs of the last-named parasite in the bloody urine of a missionary in Africa, where he had by long residence acquired the disease.

From the laboratory we are taught the well-known tests for albumin and sugar, by which all sources of error may be eliminated in determining not only their presence but the quantitative analysis as well. The pathological conditions in which these substances are excreted are at times exceedingly grave, and it is of vital importance that their presence be discovered, so that timely and judicious treatment may be instituted, or operation avoided which under such unfortunate conditions would be invariably fatal.[8]

In glycosuria the surgeon must know whether he is dealing with what Pavey designates as alimentary diabetes, in which the sugar eliminated by the urine is derived solely from the food as result of defective carbohydrate assimilation; or whether that almost hopeless condition of composite diabetes, in which abnormal disintegration is taking place, is present.

No less important is the estimate of the amount of urea which is being eliminated in a given quantity of urine. Employing the simple apparatus of Doremus with the sodium hypobromite solution,[9] within a few minutes' time, by the evolution of nitrogen gas in the presence of this, the amount of urea which is being carried off by the kidneys is readily demonstrable.

Non-parasitic chyluria (that form not due to the presence of filaria) is a rare affection, but it does exist, the fluid coagulating almost like jelly. In these conditions the microscope shows little

[1] The following process is used at the Polyclinic Laboratory in determining the presence of the tubercular bacillus in the urine and feces. The sediment is thrown down in the centrifuge, the smear dried slowly over the Bunsen burner and stained with carbol-fuchsin, which is then warmed over the Bunsen burner for three or four minutes without being dried. Then wash with water and decolorize with 5% sulphuric acid, and again wash with water. After this add 95% alcohol, which decolorizes the smegma bacillus, and again wash in water, counterstain with methylene blue, and dry. With the 1-12 oil immersion, the clusters of tubercular bacilli are readily seen.

[8] To determine the presence of albumin, the nitric acid and heat test is classical and reliable. The simplest quantitative analysis, as recommended by Hare, is to fill the tube for the centrifuge to the 10 cc. mark with urine, to which is added 2 1-2 cc. of potassium ferrocyanide solution (one part to ten); 1 1-2 cc. of acetic acid is also added. After mixing the fluids well the centrifuge is rotated until the albumin is precipitated. Every 1-10 cc. mark on the tube represents 1% by bulk of albumin: that is, if the albumin extends up to the 3 1-2 cc. mark, the albumin amounts to 35%. Fehling's test in the demonstration of sugar and the quantitative analysis by means of yeast fermentation is another important laboratory process, without recourse to which the surgeon in a certain group of cases can not satisfactorily work.

[9] Solution A, bromin and sodium bromite each 125 gm., water 1,000 cc. Solution B, sodium hydrate 400 gm., water 1,000 cc. Take of A and B each 1 part, water 3 parts. They are only to be mixed when needed for use. After the tube has been filled with the solution the pipette is filled with urine to the 1 cc., and the point carefully introduced beyond the bend. The urine in the pipette is then expelled by compression of the bulb, care being taken not to force any air into the tube.

that is pathological excepting some minute granules and oil droplets similar to those in milk. (Osler.)

The presence of blood in the urine, even in the most minute quantities, can in almost all cases be recognized by the microscope, and in those exceptional instances of hemoglobinuria in which the corpuscles have disappeared, the blood crystals of Teischmann may be recognized by the addition of a drop of strong acetic acid to a few drops of urine placed upon a watch glass. For this condition of blood pigment in the urine in which the blood cells are absent, Osler suggests the name methemoglobin. He further states that when granular pigment or darkly-pigmented urates or fragments of blood disks do not point clearly to the presence of blood, the two absorption bands of oxyhemoglobin, and more commonly the three absorption bands of methemoglobin, of which the one in the red near G is characteristic, may be determined by the spectroscope. In general, however, the red and white blood corpuscles and filaments of clot are clearly recognizable with the one-sixth objective. Even without the microscope the presence of a very minute quantity of blood distributed through the urine can be recognized by Heller's test of adding a few cc. of urine to a drop or two of strong solution of caustic soda and boiling the mixture. If blood is present a bottle-green color is produced, and the phosphates fall to the bottom of the test tube in fine flakes, tinged brownish red by the coloring matter of the blood. (Hare.)

When blood is found in the urine as a complication of papilloma of the bladder, particles of the broken-down tumor are very frequently found in the urine, and under the microscope the epithelial elements of this neoplasm are easily recognized and point clearly to the source of the hemorrhage. In hemorrhage from the kidney substance blood casts tell unmistakably of its source.

Chemistry demonstrates in the urine the presence of indican or indoxyl sulphate of potassium, a product resulting from the decomposition of albuminous products in the intestinal tract under the influence of bacteria. It is always suggestive of persistent constipation, is found in obstruction of the intestinal canal, carcinoma of the liver or stomach, in peritonitis, and is one of the symptoms of pernicious enemia. Urine containing this substance, if treated with two or three times its volume of hydrochloric acid, turns a violet color.

A careful analysis of the various casts found in the urine under different conditions is of inestimable value. Blood casts indicating not only hemorrhage from the kidney, but acute inflammatory conditions, and casts composed of pus corpuscles and studded with micrococci suggesting pyelonephritis, are most valuable results in laboratory research. It also tells us of the existence of granular casts which indicate a chronic or subacute inflammatory process in the substance of the kidney, which is accentuated when fatty casts are found, and that hyaline casts have a grave significance, as they are most frequently associated with chronic interstitial nephritis, and that the waxy variety is very common in chronic suppurative processes, usually in the bones and joints.

Today one of the most attractive subjects of laboratory research is the blood, and although hematology is practically in its infancy, many valuable discoveries have already been made, and in the proper study of a patient a knowledge of the blood is as essential as that of the urine. It may throw no light upon many cases, but the reward will be tenfold in that particular instance where the diagnosis is made definite and clear. It is necessary to know the normal blood thoroughly by constant practice in order to recognize the abnormal changes which may be present in a given case, and I can think of no more useful way of spending the time not taken up by practice than by going over these important features of laboratory technique.

A knowledge of hematology enables the surgeon to detect any form of anemia and to determine whether it is a type of blood impoverishment which can be corrected, or whether it is of the graver or more pernicious forms which would either preclude an operation or, if this were absolutely necessary, would enable him to announce to those entitled to information the gravity of the outlook. In ordinary practice it is not always essential to differentiate between a pernicious anemia or a leukemia, or whether this latter condition is present in the lymphatic or splenic-myelogenous form, for the reason that all of these graver varieties call a halt to operative measures when these can be avoided. But the anemia which comes from malnutrition, or malaria, or chlorosis can be positively diagnosticated by a study of the blood.

The richness of the hemoglobin may in a fair measure be determined by the comparative color test of the blood in proper solution, as observed through von Fleischl's hemometer. When a low percentage of hemoglobin is present, it is an indication to avoid any operative shock until the impoverished condition of the blood can be corrected by proper nourishment, by rest or by medication, when this is positively indicated. This also suggests the aid of the microscope in a further investigation as to the condition of the corpuscular elements of the blood. It is advised by Miculickz never to operate when the register of the hemometer shows less than 35, and it would probably be safer to place the standard 10 or 15 points higher. Even in the simple forms of anemia, the degenerative changes in the blood elements, especially in the red cells, are easily recognized, and are full of valuable suggestions.

When the red cells are near the normal count (about 6,000,000 to the cc.) they may still show certain characteristic deformities of individual cells (poikilocytosis) as well as variations in size in the presence of microcytes and macrocytes which appear in the field, and which are not seen in the normal blood. If the red cells are paler in color than normal, if they undergo crenation or

breaking at the edges, and do not form rouleaux, it is evident that anemia is present.[10] The danger signals are still further in evidence when nucleated red cells (normoblasts) appear, and when there is added to these either the giant red cells (megaloblasts) or abnormally small microblasts, the condition is still more serious, since these corpuscles never exist in the normal blood.[11]

Hematology further enables us to differentiate with reasonable precision between chlorosis and pernicious anemia. In the former, though pale in color, the blood coagulates rapidly, while in the latter coagulation takes place slowly, and the red corpuscles do not tend to the formation of rouleaux. The red cells in chlorosis (which are smaller and paler than normal and are frequently deformed) vary from 4,000,000 to 2,000,000, rarely falling as low as 1,000,000, while in pernicious anemia in which the average diameter of the red cells is increased, the count rarely rises above 1,000,000, and often below this. Cabot gives 1,000,000 as the average number per cmm. The white cells are also diminished, varying from 4,200 to as low as 500, with lymphocytosis as a prominent feature. Megaloblasts are found in both conditions; but, while plentiful in pernicious anemia, are rarely noticed in the milder disease, chlorosis. The more megaloblasts in pernicious anemia, the more hopeless the case.

The surgeon would be extremely unfortunate to fail in the recognition of these often obscure lesions, and, if possible, to correct them before subjecting his patient to the severe ordeal of an operation. In the early recognition of septic processes—chiefly pyogenic—surgery can no longer disregard the value of the blood count, especially the estimation of the leucocytes.

The relative number of leucocytes in a given quantity of blood, or their proportion to the red corpuscles, can be readily determined by the use of the Thoma-Zeiss apparatus which, is as well known, consists of two pipettes, one for the red and one for the white, with a well-outlined and peculiarly constructed slide or counting apparatus, and employed with the ordinary one-sixth laboratory objective. The differentiation by the use of the Daland hematocrit is not considered sufficiently exact to be satisfactory in the hands of the majority of hemotologists. It is essential in making these differentiations to bear in mind the normal conditions that at the sea level the average number of red cells per cmm. is 5,000,000 in men, and 4,500,000 in women, and 6,000,000 in the young and more vigorous adults, while the white cells average about 7,500 per cmm. for each sex.

Certain conditions not considered normal, influence the number of leucocytes since in the latter months of pregnancy they are moderately increased, and after parturition, and during the early weeks of lactation, a leucocytosis may be present, without pathological significance. After hemorrhage the leucocyte count is increased, and in diphtheria, erysipelas, trichiniasis, all extensive forms of endometritis and all acute pyogenic processes, leucocytosis exists except in those cases where the vitality of the individual has been overwhelmed by the severity of the septic process, under which condition the leucocytes no longer respond to the demand for the protection of the tissues, and are not present in the superficial blood in even normal proportions. It is probable that the application of this knowledge is more profitable at present in a study of the various lesions of the abdominal and thoracic organs. We know that in a certain proportion of cases of infection, temperature does not always indicate the increasing gravity of the lesion, while the degree of sepsis can be in great measure determined by the leucocyte count. In impaction of feces, extra-uterine pregnancy, floating kidney, gall-stone colic, renal colic, ovarian neuralgia, intussusception, volvulus, internal hernia, twisted pedicle, etc., there is no leucocytosis unless complicated with an acute septic process. In abscess of the liver the leucocyte count ranges from 12,000 to 48,000, while there is a well-marked increase in all the septic pyogenic processes of the lungs and the pleura.

In osteomyelitis the leucocyte count ranges as a rule from 15,000 to 25,000, and at times higher. Since in the early stages of this disease it is at times difficult by subjective symptoms to differentiate between rheumatism or gout, the leucocyte count is invaluable in demonstrating at once the pyogenic process.

In that very rare disease, trichiniasis, the leucocytes register sometimes as high as 30,000, but the special feature is the presence of a large number of eosinophile cells, sometimes as high as 50%, and in rare cases 67% of the total number of leucocytes being this form of corpuscle. A very considerable number of cases have been reported within the last year, in which the diagnosis had been determined by the presence of eosinophiles.

Not only can the presence of the plasmodium malariæ be recognized in the red blood cells, but hematology is already able to determine between the different varieties of the malarial parasite. It has been shown that the tertian organism takes forty-eight hours to develop and undergo sporulation; the quartan seventy-two; while the estivo-autumnal passes through irregular phases, varying from forty-eight hours to several days.

We are enabled to demonstrate also the presence of the spirochete of relapsing fever discovered by Obermeier in 1873. Although the cork screw or spiral threads are rarely seen unless the blood is examined in the height of the fever paroxysm, diplococcus-shaped bodies, believed to be the spores of this organism, are found in the periods of remission.

The time allotted has permitted hardly more than a suggestion of the methods of laboratory research, applicable in the daily routine of surgical practice. To me the moral of the lesson is that the *science* and *art* of surgery are inseparable.

[10] The average red corpuscle (normal) is 7 mmm. in diameter.
[11] A normoblast is a nucleated red cell not over 10 mm. in diameter, with a nucleas not more than one-half the diameter of the same.

THE SURGICAL TREATMENT OF GASTRIC ULCER, WITH REPORT OF CASES.[1]

BY F. B. LUND, M.D., BOSTON.

I. PERFORATING ULCER.

IN November, 1899, I had the pleasure of presenting to the Surgical Section of the Suffolk District Medical Society a patient upon whom I had operated in June of the same year for perforating gastric ulcer, the operation having been done sixteen hours after perforation, and in the presence of a general peritonitis. In view of the subsequent history of the case, a few details as to the operation are worth recalling.

The ulcer was situated upon the anterior surface of the stomach, close to the pylorus, and was infolded and sutured in a direction transverse to the long axis of the stomach, so as to avoid stricture. Owing to the extensive general peritonitis, it was necessary to drain both flanks through the wound in the epigastrium, and owing to the presence of pus in the pelvis a second incision was made below the umbilicus, and a tube and gauze passed into the pelvis. The man, when presented at the Surgical Section in November, 1899, was in good health, was engaged in hard labor and had no hernia. He continued at hard labor and in good health until early last month, and had had much better digestion than before his operation, and gained considerably in weight.

On February 14, 1901, he was overcome by gas while working in a manhole, but was rescued and resuscitated. An attack of vomiting ensued later; the same day he was seized with agonizing abdominal pain, and on the fourth day after this attack (to omit details) I operated upon him for acute intestinal obstruction by a band. On opening the abdomen found the stomach normal in size and entirely healthy in appearance. The pylorus was adherent to the under surface of the liver by firm adhesions. The bands which caused the obstruction ran from the lower or pelvic incision to the jejunum, which at the point of attachment of the second band was sharply kinked and completely obstructed. The bowel above the band was dark purple in color, greatly distended, and its muscular coat so far paralyzed that it did not contract sufficiently to pass its contents on into the collapsed ileum on relieving the obstruction. It was, therefore, necessary to open the dilated bowel by a short incision, and empty out a large quantity of liquid feces. As soon as the pressure was relieved by this maneuver the patient began to vomit large quantities of feces, which he was prevented from inhaling by inverting the table. He became very cyanotic, and his condition was extremely serious. The bowel and abdomen were quickly washed and sutured while he was struggling violently and vomiting, as it had been necessary to take off the ether when the fecal vomiting began. He stopped vomiting at about six o'clock that night, his bowels moved the next morning, and he is now having a very satisfactory convalescence.

The case is reported for its interest as to the following points: (1) The perfect health and normal digestion of the man for the year and eight months following the operation; (2) the normal appearance of the stomach found at the second operation; (3) the fact that the band which caused the obstruction was not caused by any operative procedure directed to the stomach ulcer, but by the incision in the lower part of the abdomen, which was made necessary in order to drain the pelvis on account of the general peritonitis. The case, therefore, cannot be used as an argument against operating on the stomach owing to the danger of subsequent obstruction by bands. The danger of such bands is much less in the upper part of the abdomen, where the stomach is situated; and in the now quite extensive literature on the surgery of stomach ulcer, perforating and otherwise, I have found few reports of obstruction by bands following operations on the stomach. The rarity of obstruction by bands, considering the enormous number of operations upon the appendix and pelvic organs which are nowadays performed, seems to me truly remarkable, and the danger from this cause can hardly, it seems to me, be employed as an argument against operating upon gastric ulcer.

At the time this case was reported, in November, 1899, I was able to collect 181 cases operated for perforation in gastric ulcer, since Miculickz performed the first operation in 1880, with 45% of recoveries. In the last 40 cases, which I had collected since 1897, there were 70% of recoveries. Of the 14 of these 40 cases which were operated within twelve hours, 12 recovered, or 86%.

Tinker, in his collection of 232 cases, published in July, 1899, found that of 16 cases operated within twelve hours of the perforation in the three years since 1896, only 3 died, giving a recovery percentage of 82.36.

In June, 1901, Finney, in an able report to the American Surgical Association on the subject of perforating gastric ulcer, by adding to Tinker's list 15 cases from my tables, and 21 collected from current literature, made up a general total of 268 cases, with a mortality of 48%. In the 21 most recent cases the mortality was 38%, and these were operated upon at varying times up to sixty hours after the perforation. Of the 10 of these 21 cases operated upon within twelve hours 7 or 70% recovered.

Although the criticism is just, that the published statistics of gastric ulcer may be too favorable, owing to the fact that certain operators are more apt to publish successful than unsuccessful cases, even allowing for this fact, the low mortality can hardly be other than surprising, considering the nature of the emergency. On the other hand, it must be remembered that the cases are collected from all sorts of writers under all possible conditions, and that certain series by operators of

[1] Read before the Boston Society for Medical Improvement, March 4, 1901, and the New Hampshire Medical Society, June 17, 1901.

special skill under the most favorable conditions might give even more favorable results. However, there can be no question that the mortality of the cases operated promptly; that is, within twelve or twenty-four hours of the perforation, is and will be remarkably low. The importance of such early operation cannot but be obvious on comparing perforating ulcer of the stomach with appendicitis. We are coming more and more to realize the importance of early operation on a perforation of the appendix, the perforation of which does not in the majority of cases mean a direct opening between the lumen of the intestine and the abdominal cavity, as the little organ has to be tightly closed by inflammatory swelling so that it cannot drain into the bowel before there is any danger of its perforating at all. How much more essential, then, is early operation in the perforation of a large hollow viscus, capable of flooding the abdominal cavity almost at once with septic fluid contents.

As bearing in an interesting manner upon the diagnosis of perforation, the relation of gastric ulcer to chlorosis, and the happy results of early operation, I am able to report the case of a young woman upon whom I had the privilege of operating for perforating gastric ulcer, during my service as assistant to Dr. Munro at the City Hospital last fall.

PERFORATING GASTRIC ULCER.

Emily J., age seventeen, single, a mulatto girl, born in Virginia, and occupied in housework, was admitted to the City Hospital on October 3d.

The history was that she had had "stomach trouble" for four or five years, consisting of distress after eating, frequent vomiting of acid fluid and much belching. Had marked constipation. Did not menstruate until sixteen, when she menstruated once, and not again for six months. After that menstruated regularly until time of present illness. Menstruation scanty but not painful. For the past year had had dyspnea and palpitation. For the past year the stomach symptoms had been worse, and the pain was always aggravated by food. For a week before entrance the pain got gradually worse, and she noted tenderness in the epigastrium and headache. The day before entrance the pain was at times so severe that she could not sit up straight. During the week she ate little because it aggravated the pain. She had kept at work all this time, and on October 3d was dressing to go out, when, shortly after 1 P.M., the pain suddenly became so intense that it doubled her up, and she was unable to move. She waited three hours for somebody to come and put her to bed. Half an hour after the onset of the pain she vomited. The vomitus was dark, like coffee-grounds. No coffee-ground vomiting previously. Felt cold but had no chill. No subsequent vomiting. The pain continuing, a physician was called, and she was sent to the City Hospital, where I saw her at 11 P.M., or ten hours after the visit of the pain which probably signalized the perforation.

Examination showed a slight, anemic-looking mulatto girl, in great pain. Gums and conjunctivæ pale. Tongue clean and moist. Heart showed a soft systolic murmur at second right interspace and apex. Pulmonic sound accentuated. Temperature 102.6°, pulse 104 and of good quality. Abdomen slightly distended. Slight general spasm, but very marked tenderness in epigastrium. Less marked tenderness over whole abdomen. Tympanitic everywhere.

Operation. — Under ether. Incision 1½ inches long, median line, half way between umbilicus and ensiform cartilage. Turbid serum free in peritoneal cavity. Incision then prolonged downwards for 3 inches. Flakes of fibrin found on anterior surface of the stomach. On drawing the stomach down and out, on the anterior surface near the cardia, lightly adherent to the liver, was found an indurated area 1½ inches in diameter, in the centre of which was a minute perforation, through which gastric contents escaped. The stomach was then folded on itself parallel to the long axis, so as to include the perforation, and fastened by two rows of fine silk sutures. General abdominal cavity thoroughly washed out, and a gauze wick passed down to the line of suture in the stomach. The greater part of the abdominal wound was closed by sutures.

After the operation the young woman had no serious symptoms, and on the following day we felt justified in giving a good prognosis, in view of the slight spread of the peritonitis found at the operation, and the favorable statistics of these cases when operated upon early. The patient bore rectal feeding so well, and her condition was generally so satisfactory, that she was given nothing but a little hot water by mouth for ten days, when she got rather weak and developed a left femoral phlebitis. Nourishment by mouth was begun at once, and the attack, which was a slight one, quickly subsided. She left the hospital in five weeks. Since then her diet has been under supervision, she has gained in weight and strength, and her digestion has been excellent.

The chief points of interest in this case seem to me to be:

(1) The excellent history of chlorosis with delayed menstruation.

(2) The history of the gradual aggravation of the symptoms of the ulcer during the week preceding perforation, which extension probably coincided with a gradual increase in the depth and extent of the ulcer, and possibly with the formation of light fibrin deposits upon the peritoneum covering it. These symptoms were sufficiently marked, it would seem, in case they had been observed by a physician to suggest a "preperforative stage." In case such an ulcer could be operated upon when threatening to perforate, but before actual perforation had taken place, as would seem possible in such a case as this, ideal results ought to be attained.

(3) The fact that the aggravation of the symptoms, by lessening the ingestion of food, probably caused the stomach to contain little food at the

perforation, a condition which, with the small size of the perforation, probably accounted for the slight extent of the surrounding peritonitis.

In regard to the operation, it was a remarkably easy one, and could not be compared in difficulty with the complicated dissection which is often required in the removal of an appendix buried in adhesions. To draw the stomach out through an abdominal wound, infold and suture an ulcer on an easily accessible portion of its anterior surface, cannot be considered a difficult procedure, and seems to be one which, in the absence of a general peritonitis, — which condition can only be secured by early operation,—ought to be almost uniformly successful.

It is fortunate for the surgeon that, although a vastly larger number of ulcers of the stomach are situated upon the posterior than the anterior wall, perforation of the ulcers of the anterior wall is much more frequent than those of the posterior. This fact is undoubtedly due to the greater fixedness of the posterior wall, affording more frequent opportunity for the formation of adhesions which prevent perforation. According to Pariser and Lindner, quoted by Finney, of 200 cases of gastric ulcer, 190 will be on the posterior wall and 10 on the anterior wall; of the 190, 4 will perforate; of the 10, 8½ will perforate.

II. OPERATIVE TREATMENT OF CHRONIC OR INTRACTABLE ULCER OF THE STOMACH.

There can be no question that a large proportion of gastric ulcers recover temporarily, at least, under medical treatment; consisting of rest in bed, rectal alimentation, careful feeding by the stomach, regulation of the bowels, etc. According to the most favorable set of statistics,— those presented by Leube at the German Surgical Congress in 1897,— 74% got well under five to six weeks of medical treatment. These statistics were based on the unusually large number of 556 cases personally treated by Leube, and may be said to represent the most favorable results of medical treatment. Of the 36% of cases which did not recover, 93, or 21.9%, were improved; 7, or 1.6%, were unaffected by treatment; and 10, or 2.4%, died. According to the most favorable view of the results of medical treatment, then, there are 25% of the cases in which the surgeon may legitimately interest himself in regard to whether he can afford by operative measures any better promise of relief or cure.

The percentage of cases which do not yield to medical treatment is likely, in fact, to be somewhat greater than these statistics indicate, for the reason that in view of the fact that in the absence of hemorrhage an absolute diagnosis of ulcer cannot be made, a fact which was pointed out by Miculickz as affecting the value of Leube's statistics. Of Leube's cases only 19.5% presented the symptoms of hemorrhage either before or after the beginning of treatment. It is, therefore, possible that a variable number of the cases reported as cured were not actually cases of gastric ulcer.

In regard to the actual final results of the medical treatment of gastric ulcer, the results obtained by Greenough and Joslin, in their investigation of 114 cases treated at the Massachusetts General Hospital between 1888 and 1898, are of great interest and value. They found that 80% of these 114 cases were discharged from the hospital cured or relieved, but that at the end of an average period of fourteen years only 40% remained well, and that the mortality in the same period was 20%. This mortality, and the failure to obtain a lasting cure in 60%, indicate that the statistics of medical treatment based on a longer interval of time are not nearly as favorable as those based on the time of discharge from hospital.

Now what can the surgeon do for these cases; namely, the chronic relapsing cases which do not yield to medical treatment? Can he at an operative risk of less than 20% afford a promise of permanent relief of more than 60%? Even Leube, whom Rodman characterizes as the most optimistic of medical men, states that if an ulcer does not yield to one period of four to six weeks' treatment it is not likely to be benefited by a second attempt.

The mortality from the chronic and intractable cases of gastric ulcer, which are the ones which would come legitimately into the hands of the surgeons, would probably be considerably higher than 20% or 25%, and therefore a surgical mortality of less than 20% would be a favorable showing.

The surgical measures which may be employed in these cases may be classified as follows:

(1) In favorable cases, that is, when the situation of the ulcer and the condition of the patient permit it, the surgeon may excise the ulcer and suture the defect in the stomach, thus getting rid of the diseased tissue and affording the most favorable conditions for healing.

(2) In cases where the ulcer is situated near the pylorus, he may combine excision of the ulcer with pyloroplasty, thus relieving the constant irritating spasm of the pylorus, which does so much to keep the ulcer in an active state.

(3) In cases where excision is difficult, from the situation of the ulcer or the condition of the patient, he may by the operation of gastro-enterostomy ensure a free passage of the stomach contents into the intestines with the minimum of work on the part of the stomach walls, and the maximum of rest, therefore, for the ulcerated surface and infiltrated surrounding tissue.

Now what is the mortality of these various procedures? Heidenreich estimates the mortality of gastro-enterostomy for ulcer at 16.4%, and Miculickz makes the forcible statement that the danger to life from gastric ulcer is at least not less, but probably far greater, than that from a complete modern operation.

In regard to the more radical operations of pylorectomy, partial gastrectomy and excision of the ulcer, the tables presented by Rodman at the meeting of the American Surgical Association

last June, make what seems a remarkably favorable showing. He had been able to collect from literature and extensive personal correspondence detailed reports of 40 pylorectomies, partial gastrectomies and excisions, with 6 deaths, or 15%; which, considering that it includes all the cases reported since 1881, when Rydygier performed the first operation of the kind, is extremely satisfactory. It is also to be remembered that this list includes several cases in which the operation was done for suspected malignant disease, so that rather extensive gastrectomy was done; a fact which renders the case still more favorable. We must also not forget that the majority of these cases were referred to the surgeon late in the disease, when repeated vomiting and long starvation had rendered the patients poor subjects for surgical intervention.

A most important contribution to this subject was made by Mayo Robson, who, in his recent Hunterian Lectures, reports 188 operations upon the stomach, with a mortality of 16.4% for gastric ulcer, excluding perforation and hemorrhage. He concludes his paper with a plea for earlier resort to surgical measures, to which his standing and experience give authority. "My own experience and a careful study of the subject," he says, "would lead me to say that the time has not yet come for a sweeping change to be made in the treatment of uncomplicated gastric ulcer, except in the way of more rigid and prolonged medical treatment; but that when the ulcers prove intractable, or when complications supervene, medical treatment should give place to surgical treatment at a much earlier stage than has hitherto been the custom. It is unfair to the surgeon to hand over to him moribund patients, as is at present so often done; and it is, in my mind, unjust to the patient to persist in dosing them with medicine, or otherwise treating palliatively cases that can be only benefited or cured by surgical means."

The statistics published by Miculickz in 1897, comprising the results of his own, Czerny's and Billroth's (von Hacker's) clinics, show in an instructive manner the decrease in the mortality from operations for benign stricture of the pylorus and uncomplicated stomach ulcer. Before 1890, in the three clinics, 27 of these operations had been performed, with a mortality of 13, or 42%. From 1891 to October, 1896, there were 38 operations, with 7 deaths, or 18.3%. Between October, 1896, and March, 1897, Miculickz performed 10 of these operations *with no mortality*. In cases collected from all sources, including the above, from 1895 to the beginning of 1897, there were 60 cases, with 6 deaths, a mortality of only 10%, while the total mortality of all cases, from the first reported up to 1897, 238 in number, was 21.8%.

To the literature of the excision of chronic ulcer of the stomach, in a case in which the character and severity of the symptoms lead to the suspicion of malignant disease, and therefore to early operation with most fortunate result to the patient, I am able to contribute the following case, which I had the opportunity of operating upon, owing to the kindness of Dr. J. C. Munro, in his service at the City Hospital last autumn:

J. S., thirty-seven years of age, born in Ireland, and a coachman by occupation, was admitted to the hospital on November 21st. His history showed that for the past year he had suffered continually from indigestion, with occasional vomiting. He had had to be careful about his diet, a matter which was difficult, considering the character of the boarding-houses where he lived, and had had frequently to change his boarding-place. Numerous common articles of diet he could not keep on his stomach, and he was totally unable to digest meat which had any fat on it. For the two months before his entrance to the hospital he had been unable to eat, on account of pain and distress in the epigastrium caused by food, and had had frequent vomiting of bright blood and coffee-ground looking material. He had lost considerable weight. On physical examination he was found to be pale, emaciated and cachetic looking. During three days, in which he was restricted to a diet of beef-juice and predigested milk, he suffered from epigastric pain and occasional vomiting. A test breakfast showed the absence of hydrochloric acid from the stomach contents, and the presence of lactic acid. On November 26th, as the vomiting still continued, he was placed on rectal alimentation, under which treatment his condition somewhat improved and the vomiting ceased.

The diagnosis lay between ulcer of the stomach and malignant disease; and in favor of the latter were the man's appearance, cachexia, emaciation and the absence of hydrochloric acid from the stomach contents. At any rate, the probability of malignant disease was strong enough to indicate exploratory operation, in view of the slight danger of exploration, and the fact that if such disease were present, the very earliest operation alone could afford any hope of cure. Therefore on November 30th he was etherized, and a short median incision made above the umbilicus. With the finger a mass was felt in the lesser curvature of the stomach, whereupon the incision was prolonged five inches, the stomach drawn as far as possible outside the abdomen, and the surrounding area walled off with gauze. On the lesser curvature was found an indurated mass about two inches in diameter, surrounded by a brawny, infiltrated area, which extended to within three-quarters of an inch of the pylorus, and two-thirds of the distance to the cardia. This infiltrated area extended further onto the anterior than the posterior surface of the stomach. The mass at its center could be felt to be an ulcer, with very thick indurated irregular edge, which felt exactly like a malignant growth.

Therefore excision was proceeded with by first tying the gastro-hepatic omentum with catgut, and then applying long clamps to the stomach wall well outside the indurated area, both above and below it, and excising the mass with scissors. The clamp on the cardiac side slipped, and the larger vessels

on that side had to be clamped separately. The very large gap left by removing the mass was closed in a longitudinal direction by two layers of silk sutures, the first layer consisting partly of Cushing continuous suture and partly of interrupted sutures, so placed as to control the bleeding vessels. This first layer included only the muscular and mucous coats. As the suture proceeded toward the pylorus it was found that so much of this narrower portion of the stomach had been excised, that the longitudinal suture would completely obliterate the lumen, so that the pyloric portion was brought up transversely across the end of the longitudinal suture, making a plastic, which restored the lumen excellently well, but left a T-shaped wound. The operation was finished by a continuous Cushing suture of the peritoneum along the whole line, infolding the layer, and fortified at the angle of the T by a few interrupted sutures. At the end of the operation the stomach was about the size and appearance of the upper part of the small intestine, its caliber being, perhaps, a little greater than that of the slightly dilated duodenum. Two enlarged glands were removed from the lesser omentum, close to the aorta. The operation was finished by suture of the abdominal wound, two gauze wicks being carried down to the suture line through its upper angle.

There was little or no shock attending these procedures, which lasted an hour and three-quarters. The pulse at the close was 90, full and regular. The stomach had been washed out the evening before and the morning of the operation. The convalescence was uneventful. He did not vomit even on coming out of ether. He was placed on rectal alimentation, and on the fourth day the administration of liquids by mouth was begun. On the seventh day the wicks were removed. There was a moderate discharge from the sinus after this, which for three or four days had the odor of gastric contents. This, however, soon ceased, and four weeks after the operation he was up and about, and his diet was extended to include soft solids.

Five weeks after the operation he was distinctly gaining in weight and general condition.

On January 16th he left the hospital. He was then eating three fair meals a day, and only had distress after eating an unusually large amount. His diet was carefully supervised in the Medical Out-patient Department. He has since been hard at work washing carriages. He has steadily gained in weight and general condition, and now feels well, works hard, and is able to digest fat meat and various foods, which he could not manage before the operation.

The ulcer, when excised, was found to be about one and one-half inches in diameter and three-eighths of an inch deep, with a gray sloughing base, and hard, indurated, grayish edge. Sections taken from various parts of its edge showed extensive growth of old fibrous tissue, infiltrated with leucocytes, and lymphoid and plasma cells. There was no evidence of malignant degeneration in any part of it.

We had to do with a large ulcer, which was evidently chronic, as shown by the amount of fibrous tissue in the walls, and which was situated so near the pylorus as to be evidently troublesome by causing spasm of that muscular ring. Its appearance and position showed that it was of a kind which would have proved rebellious to treatment, and the condition of the patient since the operation has left little to be desired. Therefore I cannot help but feel that, although the operation was performed under the probable diagnosis of malignant disease, it has resulted in ridding the man of a serious trouble more quickly, and perhaps, everything considered, more safely than any other way. For his condition at any time, either during or after the operation, did not suggest danger, and to my mind confirmed the statement of Miculickz, quoted above, that the danger to life from a complete modern surgical operation is less than that from the disease.

THE SURGICAL TREATMENT OF HEMORRHAGE FROM GASTRIC ULCER.

In the treatment of hemorrhage from gastric ulcer, we approach the most difficult, and yet the most interesting, subject connected with the surgery of this condition. Hemorrhage, which occurs as a symptom in 80% of cases of gastric ulcer, is fatal in only about 5% of these cases, its fatality being variously estimated at from 3% to 11%.

In about 50% of the fatal cases, death is due to grave anemia and exhaustion from frequently repeated slight hemorrhages; and heretofore, so great has been the confidence in medical treatment in this class of cases, that the patients have been, for the most part, brought under the surgeon's care when exhausted and emaciated to the last extreme. In this class of cases, namely, the small and frequently repeated hemorrhages, which is the one most amenable to surgical treatment, Rodman's tables give 31 operations, with 5 deaths, the low mortality of 16.1%. In 12 gastro-enterostomies for this condition there has been no mortality, which Rodman rightly characterizes as a most favorable showing, and one which should lead to more frequent operation in cases of this kind. Robson is also in agreement with Rodman, in advising surgical treatment in cases of this character, and it seems to me that, in view of these results, none of us would be justified in letting a patient sink into a critical condition from repeated gastric hemorrhage without resorting to surgical measures.

In regard to the treatment of the severe and copious hemorrhages, which reduce the patient at once to a condition of grave anemia, we have a more difficult question to deal with; and on examining the results of the surgical treatment of such cases, we find that the mortality has been high — 64.2%, according to Robson; 37.5%, according to the more accurately analyzed tables of Rodman. Now, in view of the fact that death rarely results from a first hemorrhage, even if severe, these figures contra-indicate operation during the first attack of severe hemorrhage, and it would seem

as if the treatment should be limited to rest, opium and salt infusion, as in hemorrhage elsewhere.

When, however, a first copious hemorrhage has been recovered from and been followed by a second, is a policy of inaction justified? Rodman, on the basis of a careful examination of 60 reported cases, concludes, I think rightly, that it is not, and that a too long delay after the second hemorrhage is hazardous. He quotes the case of Elder, which was lost by a too long delayed operation, and those of Tubby and Michaux, which would, in all probability, have recovered had they been operated upon after the second hemorrhage. Successful operations, after the second hemorrhages, have been reported by Armstrong, Andrews and Hirsch, whose cases were all operated upon in a condition of extreme anemia, and the cases of Cazin, Robson and Roux recovered when operated upon after three severe hemorrhages. Rodman points out that the mortality of 37.5%, although high, is not a prohibitory one, when we consider that the cases so far operated upon have been extreme ones, and only turned over to the surgeon when death seemed inevitable without surgical intervention.

Another reason for intervention in hemorrhage is the frequency with which a bleeding ulcer subsequently perforates, and the fact that operations for hemorrhage generally cure the ulcer and accordingly prevent subsequent perforation.

In favor of an active, rather than a waiting, policy in the presence of acute hemorrhage from the stomach, may be cited the experience which we have all been through of recent years in connection with intra-abdominal hemorrhage from extra-uterine pregnancy. The policy formerly pursued in the most acute hemorrhages, when the surgeon found the patient pulseless, sweating, restless, and on the verge of dissolution, was to stimulate freely and await reaction before submitting the patient to the so-called shock of an abdominal operation. We all of us remember, in recent years, papers by some of our best surgeons advocating this policy; but we have since found that it is safer to stimulate a bleeding patient *after* rather than *before* a bleeding artery is tied; and that by the aid of copious infusions of salt solution, begun at the same time with the operation, we can spend the ten minutes required to open the abdomen, pull out, tie off and remove the tube and sew up again better than inactively allowing the bleeding to continue; and that, so far from there being any shock connected with the operation, the patient generally has a better pulse at its close than at its beginning, and that in a surprisingly large number of cases recovery ensues.

In spite of the greater complication of the measures required in dealing with a bleeding ulcer of the stomach as compared with a ruptured tube, I cannot but feel that, by the aid of salt infusion and stimulation, such as prove so successful in intra-abdominal hemorrhage from other causes, measures can be practiced which will save from death a certain number of even the most desperate cases.

We must acknowledge that operation for hemorrhage from gastric ulcer is by no means as simple as that for removal of a ruptured Fallopian tube; yet exploratory operation will be sure to reveal a certain number of cases in which simple measures will suffice to stop hemorrhage; and in case the measures directed to the actual control of the bleeding artery would prove too long and tedious for the patient's strength, the surgeon may perform a gastro-enterostomy, thus aiming to control the hemorrhage by placing the stomach at rest, an operation which has been most successful in a majority of instances of gastric ulcer with and without bleeding.

The steps of an operation for hemorrhage from gastric ulcer, as far as they can be formulated from personal experience in operation for other complications of gastric ulcer (I have had no opportunity to operate for hemorrhage), and from a careful study of the measures adopted in the reported cases, would be: (1) Median laparotomy above the umbilicus; (2) drawing the stomach as far as possible out of the wound, and a careful examination for any area of discoloration or induration which might point to the location of the ulcer. In case the ulcer were located in the anterior wall on the pylorus or the first part of the duodenum, it should be excised and the opening quickly sewn up; if near the pylorus, according to the Heinicke Miculickz pyloroplastic method, so as to prevent subsequent pyloric contraction. If on the posterior surface, the same procedure might be adopted, in case the ulcer could be readily exposed by drawing the stomach out and turning it upside down on the abdominal wall.

An ulcer on the posterior surface, not accessible in this manner, might be treated by making an incision through the anterior surface of the stomach, drawing the ulcer up into the shape of a cone and ligating *en masse*, and perhaps, after suture of the anterior opening, reinforcing the fold made at the base of the cone by two or three Lembert sutures. When the ulcer can not be easily reached, and directly dealt with, as when it is near the cardia on the posterior surface, or where extensive adhesions exist, it would seem much wiser to perform gastro-enterostomy as quickly as possible, and trust to the rest from muscular movement of the stomach to control the hemorrhage. This operation is also to be selected without question in multiple ulcers, or those cases, of which several have been reported, where it is impossible to find the bleeding point.

Measures directed to tying the artery *in situ* have proved lamentable failures, owing to the friability of the tissues rendering such procedures tedious and unsuccessful, and the use of the actual cautery has also proved a failure and been followed in one case by subsequent perforation.

A procedure which has suggested itself to me as worth consideration in a case where a patient was *in extremis*, and the indications were to stop

the bleeding and stimulate, and, where the ulcer could be reached, would consist in opening the abdomen and placing clamps on either side and below the ulcer, or drawing it up into a cone and ligating *en masse*, leaving the clamps *in situ*, the ligature in position. Then, after twenty-four or forty-eight hours of stimulation, if the heart responded and the condition made it possible, the wound could be reopened and the conditions dealt with as found. In view of our experience with extra-uterine pregnancy, it would seem at least possible that a desperate case might in this manner be occasionally saved.

To conclude with a brief summary of the indications for surgical treatment of gastric ulcer, I would say:

(1) That in perforation immediate operation is absolutely indicated.

(2) That in cases in which the symptoms fail to yield after medical treatment for a reasonable period, operation, consisting either of excision of the ulcer or gastro-enterostomy, should be performed, and this before the patient has become so exhausted as to render surgical intervention dangerous.

(3) In hemorrhage, where slight, frequently repeated bleeding promises to produce grave anemia or exhaustion, similar early operation should be done.

(4) Where a patient has suffered more than one copious hemorrhage, operation should be performed, and the extent and nature of the procedure should be decided upon according to the power of the patient to withstand operative manipulations, and the conditions found during the progress of the operation.

In this paper only active ulcer and its complications have been considered, and the after effects of ulcer, such as pyloric contractions, hour-glass contractions, and adhesions, which also furnish a wide and constantly increasing field for surgical intervention, have been purposely left out of account.

IDIOPATHIC ABSCESS OF THE KIDNEY.[1]

BY A. T. CABOT, A.M., M.D., BOSTON,

Surgeon to the Massachusetts General Hospital.

ABSCESS formation in the kidney may come about in a variety of ways.

(1) It may be due to injury. When the injury is of a perforating character the infection may reach the kidney from without, or from some wounded coil of intestine. Occasionally an injury which does not open communication between the kidney and some infected area causes an abscess; and this comes about by the conveyance of infection through the blood channels. The injury, by bruising and lowering the vitality of the tissues, furnishes a nidus in which micro-organisms circulating in the blood may find an opportunity for growth.

(2) An abscess may be induced in the kidney by the direct extension of inflammation from contiguous parts.

(3) An inflammation in the pelvis of the kidney often extends through the urinary tubules into the substance of the organ, and in this way abscesses of greater or less size may arise. The pyelitis which in this way precedes a pyelonephritis may be a primary affection, or may be secondary to inflammations in the lower urinary tract. Such extensions of inflammatory processes through the urinary passages make an interesting chapter in the study of renal disease.

I pass over these three most common methods of origin of renal abscess with a mere mention, because I wish to devote this short paper to a consideration of the fourth method of kidney infection, namely, through the blood.

Suppurative inflammations induced in the kidney by organisms brought to that organ by the blood are extremely rare, if we except those abscesses which result from the action of tubercle bacilli. These also I leave at one side. For the subject of genito-urinary tuberculosis is a large one, and a consideration of it here would completely overshadow the subject to which I now especially wish to draw your attention, which is the acute idiopathic abscess of the kidney, dependent upon the action of some of the more properly pus-producing organisms.

The parasites that we have especially to consider in this connection are the streptococcus, the staphylococcus pyogenes aureus, the bacterium coli commune, the pneumococcus and the typhoid bacillus. All of these micro-organisms circulate freely in the blood, and probably most of them are eliminated in some degree by the kidneys. That this is the fact in regard to the typhoid bacillus has been abundantly shown. The infection of the kidney probably comes about as a so-called terminal infection, in which little capillary tufts are plugged by emboli containing the micro-organisms. The greater number of cases of this sort occur in the course of general infections, such as pyemia and septicemia, when abundant infective material is circulating through the vessels. Infections arising in this way usually occur towards the end of life, and both kidneys are usually involved. The depressant effect of the toxins in the blood diminishes the force of the circulation, and thus enfeebles the nutrition of the tissues and makes them less resistant to the invasion of micro-organisms. The functional activity of the kidneys is also interfered with, so that the bacteria are less rapidly eliminated through the capillary loops. Conditions are thus favorable for a clogging of fine vessels and an infection of the tissues about.

The direct implantation of infective material in the kidneys is made still more easy where the heart is involved in the septic process. An ulcerative endocarditis throws into the circulation little septic clots which are too large to pass vessels even larger than capillaries, and wherever these lodge an abscess is pretty sure to form.

[1] Read before the Boston Society for Medical Improvement, March 4, 1901.

In all of these forms of inflammation the renal suppuration is secondary, and a primary ulcerative process is to be sought for, from which the general infection has been started. It is usual in these cases to find abscesses in both kidneys, and not infrequently in other of the parenchymatous organs. As death usually results in such conditions, the pathological nature of the process has been thoroughly studied and is well understood.

While the above is an accurate statement of the usual course and character of these infective, metastatic processes in the kidney, it sometimes, though rarely, happens that an abscess or abscesses which are probably metastatic in origin occur in but one kidney. Instances of this sort are on record in which, death resulting, no source of infection could be found, and in which, therefore, it was once customary to regard the abscess as idiopathic in character.

The cases so interpreted, however, occurred at a time when pathological examinations were less searching than at present, and it is reasonable to suppose that small points of infection in the intestinal mucous membrane or elsewhere might well have been overlooked.

After having thus glanced over the pathology of such cases, I wish to report an observation of a patient affected by an extremely septic process of one kidney in which the infection was due to a pure culture of colon bacillus. The case is interesting, both on account of the rarity of the process, and also because it illustrates the occasional success of active surgical interference in such conditions.

R. A. R., thirty-one years of age, was seen by the writer on May 22, 1900, in consultation with Dr. W. O. Hunt, of Newtonville. The patient enjoyed good health up to the previous February, when he had a chill followed by moderate fever. He had at this time pain in the back, running down into the back of the left thigh. After two days spent in bed, the temperature became normal and the pain disappeared, and he was quickly in his usual state of health. On the 13th of May he was seized with pain in the back, mostly on the right side. This pain presently radiated down into the groin and testis. It was of a severity to require mild opiates for its relief. He had a moderate chill at this time, but was unaware of fever until the 17th of May, when he began to have high fever accompanied by vomiting. Dr. Hunt was now called, and he found the patient mildly delirious with frequently recurring chills, the temperature jumping from 97° F. to about 103.8° F. An examination of the urine showed it to contain albumin and pus in a moderate amount. For twenty-four hours before the consultation he had had no chills, but the ups and downs in temperature had continued. Upon examination, the right kidney was found to be enlarged and tender, the spot of acutest tenderness being in the back. Nothing abnormal could be detected elsewhere by physical examination. The diagnosis of an acute septic inflammation of the right kidney was made, and operation was advised. In order to carry out this recommendation the patient was removed to the Massachusetts General Hospital.

Examination of the urine at this time showed it to have a specific gravity of 1.017, and to contain a considerable sediment of pus and some blood.

On May 23d the patient was etherized and an incision was made in the lumbar region over the point of greatest tenderness, just outside the quadratus lumborum muscle. On opening the fat capsule the tissues within were found to be edematous, and on reaching the kidney a prominent soft area was found, which being incised gave exit to considerable quantity of blood-stained pus. The finger introduced into this cavity broke through softened tissue into what appeared to be the pelvis of the kidney. Another similar abscess was found and opened in the upper part of the kidney. Drainage tubes were introduced into both cavities, and the wound was packed rather snugly to check the hemorrhage which was considerable.

Cultures taken during the operation showed the pus to contain a pure culture of bacillus coli communis. This operation was followed by immediate improvement, but the temperature remained irregular for almost a month. The patient showed but moderate powers of recuperation, and his recovery of strength was slow. On July 18th he reported at the hospital with the wound entirely healed, and his general condition greatly improved. No examination of the urine was obtained at this time, but had no symptoms indicating any persisting inflammatory condition.

He was heard from again in January, 1901, when his health was excellent.

The recovery of this patient precludes the possibility of knowing the precise manner in which the infection occurred. There was no evidence to indicate a probable primary source of infection. In the absence of any external lesion, through which micro-organisms might enter the circulation, it is plain that we must suspect the alimentary canal of having afforded somewhere a weak spot through which the colon bacilli effected an entrance into the blood vessels. Such an explanation is in accord with previously observed facts.

In regard to the treatment of such conditions there seems little or no room for difference of opinion. When the diagnosis of an acute septic process in the kidney is established, the evacuation of the pus should follow close upon the conviction of its existence.

In the presence of chills, high and variable temperature and delirium, together with the local symptoms of pain in the renal region, and with a swollen and very sensitive kidney to be felt, the diagnosis is not difficult. In most cases an examination of the urine gives confirmatory evidence by showing the presence of pus and a small amount of blood in the urinary sediment.

If an abscess has broken into the renal pelvis the amount of pus in the urine may be very great. The only conditions which may be confounded with this are: (1) An acute exacerbation of inflammation in a tuberculous kidney; (2) an acutely inflamed calculous kidney; and (3) a

congested and hydronephrotic kidney due to mobility.

In either of the first two conditions there is usually a history of long-standing trouble. We cannot, however, rely wholly on this probability, for renal tuberculosis and calculus may be very insidious in their early stages. It is, however, extremely rare to see them take on sudden exacerbations of inflammation unless instrumentation has introduced a mixed infection into the urinary passages.

It may occasionally happen that an extremely congested and swollen movable kidney gives rise to symptoms closely simulating the above without the formation of pus.

I have, in a number of instances, seen the kidney enlarged and painful with an accompanying fever, and with nausea and vomiting, where the condition was shown to be an intermittent hydronephrosis with acute congestion. In one such case, of which I have full notes, the fever was quite high for ten days, often reaching 103° F. at night. Finally aspiration of the kidney was done to clear up the diagnosis. About an ounce of urine came at first and then the needle drew only blood. This exploration was followed by an immediate improvement in symptoms, and convalescence was quickly established.

In every case of doubt it seems to me justifiable to explore the kidney by an incision. If an abscess is not found, but only a tense, congested kidney, an incision of the capsule along the convexity will afford, usually, great relief. If there is any question of the existence of a calculus the exploratory incision will afford opportunity for a thorough search and for removal of the stone if one is found. If the kidney is movable and suffering from congestion or intermittent hydronephrosis, induced by the twisting of the vessels and ureter, it can be drawn up and stitched in the loin.

Thus the operation offers promise of relief in each and every one of the conditions which is likely to give rise to similar symptoms. It has little or no danger attaching to it, and if an abscess is found, the operation done early will stand a far better chance of cutting short the septic process than it would if it were kept as a last resort.

THE EFFECTS OF TRAINING; SECOND PAPER.

BY EUGENE A. DARLING, M.D., CAMBRIDGE, MASS.

SINCE the summer of 1899, the investigation into the effects of training, instigated by the Harvard Athletic Committee, has been carried on in several directions. In the first place, during the autumn of 1899 an attempt was made to conduct a series of observations on the Harvard football squad, similar to those carried on with the crews and reported in a previous article. In the second place, a number of examinations were made during the year of the crew men who were under observation in the spring of 1899, to determine whether the abnormal conditions developed during that period of training were permanent. Finally, during the 1900 rowing season a further study was made of the university and freshmen crews, largely for the purpose of corroborating the results obtained in 1899. Furthermore, the assistance of Prof. W. O. Atwater and Dr. F. J. Benedict, of Middletown, Conn., were obtained, by whom an exhaustive dietary and digestive experiment was conducted, the results of which are given in a separate paper. Following is a brief summary of the results obtained along the various lines of study:

I. FOOT-BALL TRAINING.

Although a large number of examinations were made, the results as a whole were not satisfactory. It was not possible to follow the individual players with any degree of completeness, owing to the irregularity of their work and the many interruptions due to injuries. The constant excitement attending the practice and games, and the noisy conditions under which the examinations had to be made, were not conducive to accurate observations. A detailed account of the observations would be largely a repetition of those previously reported, so it will suffice merely to point out the more salient features. The routine examinations were made just before the afternoon practice, so as to eliminate as far as possible the immediate effects of the playing and to get the hearts at the supposedly most quiet period. Seventeen selected members of the squad were examined one or more times, chief attention being paid to the hearts and kidneys. It was not practicable to make extended observations on the fluctuations of weight, temperature, etc.

Hearts.— Of the 17 men examined, 14 showed no marked disturbance of the heart's action, although in all the heart was somewhat larger than the normal, and in several instances there appeared to be a noticeable reduction in its size as the season progressed. Several hearts showed some irregularity in rhythm, but without abnormal sounds; and in several the first sound was somewhat harsher than normal at the apex, but not sufficiently changed to be considered a murmur. In three hearts the changes were marked enough to warrant more detailed description. The most pronounced disturbance was in the case of a man who had been an athlete for several years and had had no history of heart trouble. His general condition was excellent throughout the period of training, though once disabled by injury. On October 4th, after about two weeks hard playing, his pulse was 72 and somewhat irregular. The apex beat was in the mammillary line and there was distinct epigastric pulsation. On auscultation a loud systolic murmur could be heard at the apex. This was propagated into the axilla and was audible, though less distinct, in the second, third and fourth intercostal spaces at the left border of the sternum. On October 27th the pulse was 57 and regular. The murmur was still distinct at the apex, but was not conducted. This

improvement was thought to be due to an enforced rest of two weeks, following an injury. On November 17th, just before the Yale game, the murmur could be heard clearly at the apex and very faintly at the left sternal border. In February, 1900, three months after stopping training, the pulse was 76, regular and normal. The apex beat was about half an inch inside the nipple line and there was no abnormal pulsation. The cardiac rhythm was normal, but a faint systolic murmur was still audible at the apex.

The abnormal signs in this case were so marked and persistent, that it seems probable that there was a slight organic lesion of the mitral valve. The condition was not unlike that of one of the crew in 1899, previously reported, and as in that instance, while the hard work of the first part of the training season disturbed the heart's action to a marked degree, there was a steady improvement as the season advanced. It is not to be denied that there is a risk in allowing men with such hearts to take part in contests involving such prolonged and violent efforts as foot ball and rowing, but in the light of these cases it is difficult to predict just what the result in any given instance is likely to be.

In the other two cases of well-marked cardiac disturbance the trouble was of a temporary nature. In one the first sound was always harsh and the action somewhat unsteady, but no murmur appeared until just before the Yale game, when a well-marked murmur was audible at the apex and left sternal border. In the third case the disturbance was marked only at the first examination. This man joined the squad late, and was examined after but two days of hard practice. The chief abnormal sign, beyond enlargement of the cardiac dulness, was a loud blowing systolic murmur at the left border of the sternum. At subsequent examinations this gradually became fainter, and after four weeks it disappeared entirely.

The condition of the heart immediately after playing a hard game was studied in a number of instances. The effects as a rule were like those observed after hard rowing; that is, an increase in the area of dulness, increased pulse rate up to 150 or even more, a roughening of the first sound at the apex, and very often a faint blowing systolic murmur heard most distinctly in the pulmonic area. In vigorous hearts these signs were of brief duration, and were interpreted as indicating merely a passing dilatation. The examinations were all made with the man first standing erect and then with him lying supine. In several instances, but not in all, lying down caused an immediate drop in the pulse rate. In one case, standing, it was 144; lying, it at once fell to 64; standing a second time it rose to 112, and again lying it fell to 68. The normal rate for this man was about 68, and his heart never showed any other disturbance. In a second case the pulse rate fell from 120 to 72 on lying down, and in a third case from 108 to 72. Other cases showed no marked effect from changes of position.

Kidneys.— The urines of 16 members of the squad were examined one or more times during the training season. In each instance the full twenty-four-hour amount was collected and measured, and the specific gravity, percentage of urea and total urea were determined. The specimen was then tested for albumin and the sediment examined microscopically. The average daily renal excretion was 1124 cc., specific gravity 1.027, urea percentage 3.30, and total urea elimination 36.2 gms. In 6 cases out of 16 albumin was present in small amount at one or more examinations and was always accompanied by hyalin and granular casts, an excess of leucocytes and occasionally by red blood corpuscles.

A number of additional examinations were made of urine passed immediately after hard playing, and in every instance considerable amounts of albumin were found (from $\frac{1}{10}$% to $\frac{1}{5}$% Esbach), together with many casts, and usually red blood corpuscles.

II. COMPARISON OF EFFECTS OF ROWING AND FOOT BALL.

On the whole, the effects of foot-ball training are not markedly different from those of rowing, though the departures from the normal are not as great. This is readily explained by the intermittent nature of the effort in foot ball. The game consists of a series of exertions, each one exhausting, but brief. The intervals of rest occupy a large portion of the time of play. This is in marked contrast to rowing, in which the periods of effort are far more prolonged, and the exertion, while less violent, is continuous. In both sports the effects of training appear to be to accustom the heart, kidneys and other organs to the extraordinary demands, so that as the season progresses they do their work more easily.

III. FURTHER OBSERVATIONS ON THE EFFECT OF ROWING.

During the 1900 rowing season a second series of examinations were undertaken, similar to that of the preceding year, with the object of verifying the facts then ascertained. The general effects on the weight, temperature, heart, kidneys, etc., were in all important points the same, and need not be described again at this time. Two events, however, occurring at the very end of the training season, were of great interest from the physiological point of view. One was the effect on the crew as a whole of the accident which deprived it of its stroke and captain four days before the race, and the other was the collapse of the substitute stroke during the race. On the Sunday preceding the Thursday of the race the captain twisted his right ankle, fracturing the lower end of the fibula. Up to this time the men, with a single possible exception, had been in excellent physical condition. There had been less than the usual disturbance of digestion and other untoward symptoms which are so common during the last part of a severe period of training. The accident necessitated the substitution of a new stroke, and a great

increase in the amount of rowing above that which had been planned for the remaining days, in order to accustom the men, as far as possible, to the new arrangement. The result was a marked change in the general tone of the men. The calmness and quiet determination which had characterized them hitherto was replaced by a nervousness and restlessness, and they attacked their work with a kind of desperation. Coincidently, there was a temporary falling-off in the appetites, and in most cases some loss of sleep. The effect on the weights was striking. The men were not weighed on Sunday, the 24th, so comparison must be made with the Saturday weighings. For purposes of comparison let us take only the afternoon weights of the 7 men who were in the boat during all of the last fortnight. On June 14th, when the crew arrived at New London, the average weight of the 7 was 171.9 pounds. During the following week it fell to 169.6 pounds. It then rose once more and reached the former mark on June 23d, the day before the accident. After this it fell, on the average over 4 pounds per man, reaching 167.2 pounds just before the race. Allowance must be made for the loss of weight which always occurs before a contest. During the corresponding period in 1899 the average loss was a little over 2 pounds per man, most of this coming during the last twenty-four hours.

The excessive loss of weight may be attributed partly to indigestion, partly to insomnia, and partly to the increased work done. However, the condition of the men on the whole, just before the race, was thought to be fairly good, though not as good as it had been a week earlier. With the exception of the substitute stroke all finished the race in fair condition. One man, who was apparently all right at the finish, fainted about fifteen minutes after boarding the launch, but this was probably due largely to the fact that he lay down in the stern near the engine, where the air was close and hot. He revived after a short time, and showed no lasting ill effects.

The case of the substitute stroke deserves more detailed description. The sudden responsibility thrown upon his shoulders and the unavoidable hard work during the last three days before the race, had unquestionably affected him more seriously than any one else. He had lost about 5½ pounds and had been troubled a good deal with insomnia and indigestion. After rowing an exceedingly effective race for three miles he suddenly collapsed, and during the last mile was practically helpless and unconscious. After the race he remained in a semiconscious state for about an hour. He could be partially aroused with some difficulty, but wished to be let alone. He was then perspiring freely. His pulse was about 120 and rather weak, and respiration was rapid and sighing. The din of whistles and guns forbade a careful examination of the heart, but a superficial examination revealed nothing but a rapid, weak action. The temperature could not be accurately determined until an hour after the race, when it was 100.4° in the axilla. It was probably considerably higher than this at first, as meantime he had been repeatedly douched with cold water and had perspired freely. After reaching the quarters he swallowed a cup of hot bouillon but immediately vomited it. During the afternoon he remained quiet and comfortable but complained of great drowsiness. In the evening he was able to retain some toast with hot water.

He passed from under the writer's observation at that time; but in a letter written four weeks later he stated that, while he recovered from the immediate effects within two or three days, he had not yet entirely regained his former vigor. The symptoms described were those of collapse due to overexertion when not in perfect condition, and in all probability greatly intensified by the heat. He said afterward that he remembered feeling unusually hot before the race. He had already had an attack of heat prostration several years before, which may have predisposed him to this. The occurrence was a very unfortunate one, but it is only fair to regard it as accidental because resulting from a combination of circumstances which could not have been foreseen.

IV. AFTER-EFFECTS OF TRAINING.

Between June, 1899, and the spring of 1900, examinations were made as occasion arose of the men comprising the rowing squad of 1899, to determine, as far as possible, the after-effects of training, and particularly to study the duration of the cardiac and renal disturbances. Eight of the twelve men comprising the squad were examined and the results were practically uniform. As pointed out in another place the heart during a period of training takes on a considerable degree of hypertrophy, while the immediate effect of a severe effort like a race is an acute dilatation. The latter condition is a temporary one, and seems to become less marked with each succeeding effort if the training is successful; that is, if the man remains in good condition. The hypertrophy, on the contrary, appears to be a more or less permanent change. In the case of the racing men it is to be remembered that they did not lapse into complete idleness after breaking training, but all kept up some kind of active exercise during the summer and autumn. This of course would to a certain extent prevent the return of the hearts to normal size.

It must not be supposed, however, that hypertrophy of the cardiac muscle from training is to be regarded as an undesirable thing any more than a corresponding hypertrophy of the biceps. It is conceivable that too frequent repetition of severe efforts might result in a permanent dilatation and loss of tone instead of in a true hypertrophy; but in these eight men there was no evidence that this had occurred. In every instance, save one, the pulse had a normal rate and rhythm, the heart sounds were normal, and no adventitious sounds could be detected; in fact, the only abnormal signs to be made out were an increase in the distance of the apex beat from the median line and a corresponding enlargement in the area of car-

diac dulness. These measurements differed but little from the corresponding measurements made in June just before the race.

The only exception was in the case of the man whose heart was profoundly disturbed during the period of training, as described in detail in an earlier paper. In March, 1900, nearly nine months after stopping training, examination of this man showed an irregular pulse rhythm. There was still a murmur, audible faintly but clearly at the apex and at the left sternal border. In this case, as pointed out before, there was probably an organic valvular lesion dating back to an early illness and not attributable to training.

Examination of the urine of these eight men showed in most cases an early disappearance of the albumin and casts. One man, examined July 17th and August 10th, still presented a trace of albumin but no casts. Further tests were impossible in this case, so the duration of the albuminuria is not known.

Beyond the cardiac and renal conditions the men presented little of importance. Several stated that they had suffered from indigestion shortly after stopping training, due probably to the fact that they unconsciously continued the habit of eating large amounts of food after they had ceased to need it. Otherwise they all claimed to be in perfect health, and their appearance did not belie their words. There was an increase in weight of from three to twenty pounds, not so much during the summer as during the following winter; but this may have been simply the natural increase in fat commonly seen in cold weather.

In summary, it may be said that no ill effects, which could reasonably be attributed to training, were to be discovered nine months after stopping the training.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

ARTHUR K. STONE, M.D., SECRETARY.

Regular meeting, March 4, 1901, Dr. Walter Channing in the chair.

Dr. Fred B. Lund: In view of a case of transplantation of skin shown by Dr. C. B. Porter at the last meeting, I thought it would be of interest to present this case, showing that a favorable result sometimes may be obtained by the Tiersch method of skin grafting. This man had a skin flap taken off the back of the arm by a revolving electrical machine, the flap having the pedicle the wrong way from the blood supply. When put back in place it sloughed and left a raw surface. The only difference between this graft and the ordinary graft is that the slices of skin were cut as large as possible, and that grafting was done onto the surface of the ulna after chiselling off a necrotic layer. A graft was placed directly upon the bone, which took in very good shape. This graft was dressed not by being covered with protective, but by dry dressing, the dressing removed at the end of the second day. It practically healed by first intention. This graft was done in October, and he has been at work since November.

Dr. Lund then read a paper entitled

THE SURGICAL TREATMENT OF GASTRIC ULCER, WITH REPORT OF CASES.[1]

Dr. Arthur T. Cabot: I have been very much interested in the paper. It certainly presents a very important subject, and gives a great many points which are well worth thinking about. I have had but little experience in the treatment of gastric ulcer by surgery. I have had one case where the ulcer had perforated — I forget how many hours before. The case has been published — the perforation being a very small one, and the escape into the abdomen not of fluid contents, but of gas. The patient had been greatly troubled with flatulency, and when I saw her the most prominent physical evidence of perforation was the total disappearance of the liver dulness. The percussion note of tympany wholly covered the liver. In that case I turned in the ulcer in the way that Dr. Lund practised in his case, and with a perfectly good result. The patient made an excellent recovery.

In regard to the treatment of hemorrhages from these ulcers, I have had also but one experience. In that case the patient was transferred to my service from the medical wards after having had several very severe hemorrhages, and was in bad condition. The abdomen was opened. The site of the ulcer could be perfectly made out. It was on the lesser curvature, and, if the patient had been in decent condition, I think the operation of choice would undoubtedly have been to excise the ulcer in the manner that Dr. Lund practised in the chronic ulcer he described. The patient was not in good condition, and, as some quick operation had to be done, I tried the plan of throwing a ligature round the ulcer, taking a running stitch through the stomach wall all around the indurated area. In drawing up this stitch the ulcer was pushed inwards so that the peritoneal coat should be pulled together over it. In this way it was hoped that if there was sloughing in consequence of the strangulation of this bag-string stitch, the peritoneum should have a chance to glue together outside before the sloughing occurred. This operation was followed by several days of cessation of the bleeding which had been pretty constant before, and the patient began to get into a condition when it seemed to be possible to think of doing something more for the removal of the ulcer, when suddenly he had a tremendous hemorrhage when no surgeon was about, and died. The friable condition of the walls of the stomach in this case, and the difficulty of puckering them accurately for closing off the bleeding part, would lead me in the future, finding an equally indurated condition, to proceed to excision of the ulcer even at the expense of a considerably prolonged operation.

[1] See page 548 of the Journal.

DR. JOSLIN: I have been very much interested in Dr. Lund's paper, especially because, so far as I know, in the last two years nothing of importance has been contributed on the medical side to the treatment of gastric ulcer, and all we have to look for is in the improvement of the surgical methods.

The case Dr. Cabot spoke of I remember very well, because I was in the hospital at the time. Such a case now would, I think, be turned over to the surgeon many days, if not several weeks, earlier, because it was one of the cases of repeated hemorrhages, and statistics have shown that these cases are the dangerous ones.

In thinking of hemorrhage from gastric ulcer, it is well worth bearing in mind what Hood spoke of and what Dr. Greenough and I found to be true at the Massachusetts Hospital; namely, that women under the age of thirty do not die of hemorrhage from gastric ulcer. Of the cases of gastric ulcer at the Massachusetts Hospital, about 75% occurred in women under thirty years of age, and about 80% of these had hemorrhage. None died. In fact only one death occurred in a woman due to hemorrhage from gastric ulcer, and she was about forty-two, whereas of the 30 male patients, 4 died of hemorrhage.

DR. LUND: I was very much interested in what Dr. Joslin said in regard to young women under thirty not dying from hemorrhage from ulcer of the stomach. There is, I think, a very good pathological reason for this. Gastric ulcers fall into two types—the acute and the chronic. The acute ulcers occur in chlorotic young girls, and one finds an inflammatory infiltration of the ulcer and the surrounding tissue, not a formation of fibrous tissue. It is an acute inflammatory process, attended by rapid ulceration, and one which perfectly perforates. The majority of perforated ulcers will be found in young women; though hemorrhages are common, fatal hemorrhages will be rare. In the chronic variety, on the other hand, you get a deep indurated affair progressing slowly and forming adhesions. These ulcers get very deep, and if adhesions form, say, between the stomach and the pancreas, the latter will be invaded, and hemorrhage may take place from great arteries like the splenic artery. That is the reason those cases die of hemorrhage. It also makes it more unfavorable for surgical interference. Such ulcers have perforated into the aorta and into the heart. This difference in the kind of ulcer which is found in young women and middle-aged men is really the reason why perforation and moderately severe hemorrhage are common in young women, but not fatal hemorrhages, and why fatal hemorrhages occur more often in older patients and in men. Chronic ulcers are more generally situated on the lesser curvature near the pylorus where there are several large arteries — the coronary and the pancreatico-duodenal arteries.

DR. ARTHUR T. CABOT read a paper on

IDIOPATHIC ABSCESS OF THE KIDNEY.[1]

[1] See page 554 of the Journal.

DR. EDWARD M. GREENE: The symptoms and physical signs of abscess of the kidney are often so slight as to escape observation until the time for successful operation has passed. The real nature of the disease may not be settled until the post-mortem examination. Such a case has come under my observation, and seems to be of sufficient interest to justify a brief report.

The patient was a married man, aged thirty-four, a stationary engineer. He was a large man, of unusual health and strength, who had not been sick for the previous sixteen years. After getting overheated by a bicycle ride and cooling off suddenly, he had a mild chill, followed by fever and dull pain in the right lumbar region. Urine was scanty and high colored. These symptoms lasted only a few days, and he was not confined to bed. After a period of five weeks of slight malaise he had a second, more severe chill, followed by fever and pain in right lumbar region as before. He now lost his appetite, had occasional vomiting and considerable prostration, obliging him to take to bed. He presented a dull, mildly typhoidal aspect with thickly coated tongue, temperature of 103° and pulse of 90; there was moderate tenderness on pressure over the right kidney, but no tumor was felt, and there was no dulness on percussion. The twenty-four-hours amount of urine was 17 ounces, of high color, acid, 1,020, albumin, slight trace. The sediment showed a few red blood globules and a small amount of pus, but no casts. There were numerous bacteria in the fresh urine, but no tubercle bacilli. There were no bladder symptoms. No urethral discharge was present, and no stricture was found on examination. For the next two weeks he had normal morning temperature, but a rise of 2° to 3° every evening. He improved in strength sufficiently to be dressed and about his room. The dull pain near the right kidney continued, and was increased on moving about or sitting up. The urine had increased to one quart daily, but contained a little more pus, and a few hyaline casts appeared for the first time.

The next two weeks showed no change in these conditions; but during the following two weeks he steadily lost flesh and strength, became anemic, had night sweats and constant irregular fever. It was now ten weeks since the beginning of his illness, and I was able to persuade him to enter the Massachusetts General Hospital with a view to operation for suspected abscess of the kidney. There was still no tumor to be felt, although there was a small area of resistance to pressure and of dullness on percussion below the liver in the right hypochondrium. The blood count showed 20,500 white corpuscles.

He remained in a surgical ward for two weeks, when it was decided that "there was no definite indication for operation," and he was transferred to a medical ward. He had now lost 35 pounds in weight during his three months of illness, and was evidently in a septic condition. The tuberculin test was tried with negative result. Patient now began to have cough and shortness of breath

with pain in the right lumbar region, in the abdomen and in the back. After two weeks in the medical ward a fluctuating mass was made out just below the right costal margin, and he was returned to the surgical ward. An opening was made in the right hypochondrium, and a quantity of dirty brown, foul-smelling pus containing necrotic tissue was removed. There were no hooklets. It was thought at this time that there was an abscess of the liver. About two weeks later an opening was made in the ninth intercostal space, posterior axillary line, on account of signs of empyema, and nearly a quart of foul pus was removed. A finger introduced through the wound found an opening through the diaphragm about one inch from the chest wall. This was supposed to lead into the liver. The patient now suffered with severe dyspnea and died of exhaustion ten days after the last operation, and after an illness of fourteen weeks' duration.

At the post-mortem examination an empyema was found in the right pleural cavity, a perforation of the diaphragm; the liver, which was normal, was surrounded by collections of pus above and behind it; on the right side, in region of the kidney, a mass was found four or five inches in diameter, generally hard, but soft in places; the ureter ran from it. The mass proved to be the kidney, with pockets corresponding to the pelvis and calices, all full of pus. No evidence of tuberculosis was found. The left kidney was slightly enlarged and pale, but otherwise normal.

This case occurred in 1896. At the present time I feel sure that an early operation would have been done.

Dr. Lund: It seems to me Dr. Cabot has presented a most interesting subject, the cases of idiopathic infection, infection without known cause corresponding to the cases of osteomyelitis occurring in apparently healthy children. The organisms must enter the blood presumably by the alimentary canal, or in these days the inhalation of dust; the organisms may get into the lung, and, perhaps, enter the blood through the respiratory tract. I would like to corroborate what Dr. Cabot has said about the ease and general usefulness of exploratory operations in doubtful swellings in the region of the kidney. Catheterization of the ureters, as far as we know, in the male is difficult and uncertain. The Harris instrument is uncertain, and catheterization of the ureters, in the female, often is distinctly contraindicated owing to risk of infection and for other reasons, but exploratory incision exposes the organ, allows a careful eliminative diagnosis to be made, and direct treatment to any of the conditions found, as Dr. Cabot has said, whether a calculus, hydronephrosis due to movable kidney, or abscess; and it is not uncommon to start with an exploratory incision upon the kidney and end with nephrectomy. Certainly the exploratory part of the operation is very simple and very safe, and results in the decision of a good many doubtful cases and the cure of a great many obscure conditions.

Dr. Arthur T. Cabot: I was much interested in Dr. Greene's account of the extension of the abscess through the diaphragm. I have met with one such case where an abscess behind the kidney extended up posteriorly and made an empyema. I think that is rather a common direction for these kidney abscesses to extend if let alone.

ASSOCIATION OF AMERICAN PHYSICIANS.

Abstract Report of the Sixteenth Annual Meeting, held at Washington, D. C., April 30, May 1 and 2, 1901.

(Continued from No. 22, p. 535.)

FIRST DAY.

Dr. A. Jacobi, of New York, presented a paper entitled

UNCOMPLICATED HEMORRHAGE FROM THE PYOTHORAX.

M. C., seven years old, had been ill for about a month previous to admission to the hospital, complaining of a languid feeling, slight fever, lack of appetite, occasional cough, and some pain in the chest. There was marked dulness over the right lung and down to the fourth or fifth rib, with flatness over the base. Puncture yielded pus. The next day resection was done, and 500 cc. of inoffensive pus flowed out, unmixed with blood. Thiersch's solution was used for injection, and it returned with a little bloody pus, when all of a sudden it was followed by the flow of a large quantity of pure blood. The cavity was irrigated, and then it could be seen that the blood was oozing from disseminated tufts over the pulmonary pleura; some of these tufts were small, some quite large. The cavity was packed with gauze, and when it was removed two days later there was another slight hemorrhage, after which granulation went on in the usual way. Search for malignant tumor was negative, and there was no suspicion of tuberculosis. Dr. Jacobi said the case was unique in his experience, and furnished an additional cause for hemorrhage into the pleural cavity. A search of the literature had brought out no further information on the subject, no similar cases, and his surgeon friends had seen nothing of the kind.

Dr. A. Jacobi, of New York, reported a case of

CYST OF THE OMENTUM.

The patient was a child seven years old when admitted to the Roosevelt Hospital. Four years previously the abdomen had begun to swell; the child lost flesh and failed in health. A paracentesis was performed and 2 litres of slightly bloody serum were drawn off. The child seemed to get perfectly well, but after two years the swelling recurred, was again tapped, and again the child improved. At the time of entrance to the hospital there was a second recurrence. Three hundred cubic centimetres of bloody serum was withdrawn this time, but the operation was cut short by the tube becoming obstructed, it was thought,

by a coil of intestine. The abdomen at once swelled again, and the child was transferred to the surgical side for laparotomy. A thin-walled multilobular cyst was found containing about 2 litres of straw-colored fluid, and it was found to be incorporated with and involving the greater omentum. It was easily removed, and the patient made a rapid and complete recovery. The cyst consisted of several tissues, unstriped muscle fibres, fat and fibrous tissue in layers of different thickness traversed by enlarged blood and lymph capillaries. It was lined both internally and externally by a layer of epithelial cells.

DR. CHARLES CARY, of Buffalo, N. Y., presented

A CASE OF PNEUMONIA COMPLICATED BY PSEUDOMEMBRANOUS EXUDATE ON THE MUCOUS MEMBRANES OF THE MOUTH, TONGUE, PHARYNX, NARES, CONJUNCTIVÆ, GLANS PENIS, ANUS, ETC., CAUSED BY DIPPLOCOCCUS PNEUMONIÆ.

The case here reported is remarkable in one respect,—the occurrence during the course of an attack of acute lobar pneumonia in a boy of eleven years, of a profuse pseudomembranous exudate upon nearly all mucous surfaces of the body open to inspection. There was also evidence of extensive passive pleuritis and probably the involvement of the gastro-intestinal tract throughout its entire length. The affection terminated in recovery by lysis. The pneumococcus was obtained in pure culture from the heart's blood, the organs and the exudate.

DR. FRANK BILLINGS, of Chicago, gave a

REPORT OF THE PROGRESS OF CASES OF PERNICIOUS ANEMIA PRESENTED TO THE ASSOCIATION IN 1900, AND REPORT OF A CASE OF PERNICIOUS ANEMIA WITH DIFFUSE SPINAL CORD LESIONS WITH POST-MORTEM FINDINGS.

Of the 20 cases reported last year, only 10 were living at the time. Of this series, 4 have since died and 4 are still under observation. Of the 4 dying within the past year, only 1 was continuously under observation. This patient was on the decline when reported last May, and stayed in poor condition until October, when an improvement began which reached its height in December, and then the final decline commenced. During the period of improvement the white cell count kept pace with the improvement in the red cells and hemoglobin, and fell with the decline of the other elements just as was noted in the report of last year. The 4 cases now being observed are still on the upper curve of improvement, and the blood count and color is about normal. No nucleated cells have been found since January, 1900.

During the year 9 new cases have come under observation, all in well-to-do people, and no cause for the condition could be found. The condition noted last year, namely, that gastro-intestinal disturbance was a common accompaniment, was noted in all these cases. The history of the case with spinal cord lesions was detailed, together with the post-mortem findings. The diseased area was found to affect particularly the posterior nerve root areas.

DR. PUTNAM raised the question whether the spinal cord changes found in these cases were really essential and peculiar to pernicious anemia, and inclined to the view that they were not due to the anemia as such. He said that the changes as a rule have been scattered, and have corresponded to vascular areas rather than to the nerve root areas.

DR. OSLER remarked upon the necessity for additional study of that group of pernicious anemias in which the anemia occurs subsequent to the onset of the spinal symptoms.

DR. MCPHEDRAN and DR. MUSSER each reported cases belonging to this group, and DR. SHATTUCK gave the history of a case of pernicious anemia that followed and seemed to be associated with a severe mental shock.

DR. D. D. STEWART, of Philadelphia, reported a case of

ACUTE MILIARY TUBERCULOSIS, PRIMARILY SPLENIC.

Presumed primary tuberculosis of the spleen, whether acute or chronic, is rare, but one instance of the former being on record. Dr. Stewart's case is that of a young woman who, while in attendance of tuberculosis, developed symptoms of an acute general infection. When admitted to the hospital the symptoms were rather high fever, debility and enlarged spleen. Miliary tuberculosis was the diagnosis made by exclusion. The patient died fifty-eight days later, and until near the termination of the case there were no symptoms of involvement of other organs. Necropsy showed a greatly enlarged spleen, about one-half of which had been converted into a caseous tubercular mass. There were small miliary tubercles also in the kidneys, liver, lungs and meninges of the brain.

DR. J. H. MUSSER, of Philadelphia, Pa., presented

NOTES ON THE RELAPSING FEVER OF HODGKIN'S DISEASE.

The literature was reviewed and attention called to the paper of Ebstein on chronic-recurring fever, or so-called Ebstein's fever, and to the article in Nothnagel's system on the same subject. Dr. Musser reported 2 cases, the characteristics of which were attacks of fever lasting from eight to twelve days, and alternating with periods of apyrexia. In both cases there was increase of the glandular swellings coincident with the fever, which would rise rapidly to a great height, 105° or 106°, and after ten days terminate by crisis. In the second case cultures and inoculations failed to disclose the nature of the disease, but the patient now has pulmonary tuberculosis. Dr. Musser concludes that this form of fever is in all probability an expression of the glandular form of tuberculosis to which Hodgkin's disease probably belongs.

DR. WELCH called attention to the fact that a considerable number of cases of Hodgkin's dis-

ease have now been shown to be of tuberculous origin, and said that experience at the Johns Hopkins Hospital, where all cases of this disease had been carefully studied, had shown that a surprisingly large proportion turned out to be tuberculous processes.

Drs. Alfred Stengel, C. Y. White and Wm. Pepper, of Philadelphia, read papers on the

study of granular degeneration of the red blood corpuscles.

Granular degeneration of the erythrocyte is a condition in which this cell presents small granules, having a tendency to clump in one or more parts of the cellular protoplasm. The granules vary in size, some being as large as the granules of the eosinophilic leucocyte, others so minute as to be scarcely perceptible, and individual cells may show one or both varieties. The cell substance between these granules usually presents the normal staining properties of the erythrocyte. The granules have an affinity for basic stains and the intensity of staining is in direct proportion to the size of the granule. Attention has been called to these granules as a special degeneration only in the past few years, and Hamel and Behrendt were the first to demonstrate the frequency of this cellular change in the peripheral blood of patients poisoned by lead, and their study led Grawitz to study the blood in experimental intoxications, until he found that shortly after taking even very small doses these changes appeared.

With this in view, the writers of the paper undertook to study this granular degeneration in lead workers, and from the experimental standpoint. In animal experiments the blood was examined for some days previous to the administration of lead, which was given in small doses. The distinct granules appeared after the initial dose, usually in about three days, and indistinct granules were found after twenty-four hours. Their conclusions were: (1) That granules are a constant finding in cases of lead poison, and appear very early in cases under the influence of lead, long before subjective or other objective symptoms can be demonstrated; (2) that these granules disappear in cases of chronic lead poisoning as convalescence is established; (3) that apparently lead does not produce an immunity; (4) these granules may be produced experimentally in a very few days after the administration of lead salts.

Dr. M. Allen Starr, of New York, read a paper on

the toxic origin of neurasthenia and melancholia.

He classified neurasthenias into a variety of different types according to the predominant symptoms, and also according to the origin of the disease. Among the last was a class of cases that he believed to be distinctly toxic in their origin. They usually occur either in poorly nourished women or in men about the age of forty-five who had lived rather freely, had taken little care of their diet, had indulged in the use of alcohol and tobacco, and had neglected exercise. The chief symptoms in this form of neurasthenia, dull pressure in the head and back of the neck, sensations of fullness in the head with inability to concentrate the attention, irritability of temper, irregularities of the circulation, and general disorders of the digestion, either of the nature of acid dyspepsia or of considerable evolution of gas, with irregular and offensive stools. In these cases the urine is irregular in quantity, but at all times contains large quantities of indican. A mild state of melancholia is frequently associated with the neurasthenia. Dr. Starr believed these cases resulted from some toxic agent which accumulates in the blood, and which is manufactured either in the intestines or in the stomach, but he did not know what the toxic agent was.

Treatment consisted in a carefully selected diet, the use of remedies to stimulate liver activity and to counteract the evolution of toxic agents in the intestines, a hot bath on rising, followed by a cool sponging to stimulate the general nutrition of the body, and a carefully regulated exercise and rest.

Dr. Putnam thought that Dr. Starr had not proved his case in regard to the toxic origin of neurasthenias, and added that because a disease is cured by a certain remedy it does not follow that we have found the cause. The vicious circle in neurasthenia might be broken up by many things that had nothing to do with its formation.

Dr. Herter said that in studying the intestinal excreta he had found a definite relationship between the presence of etherial sulphates and indican and the existence of mental depression; an increased amount of these substances in the excreta is accompanied by a greater degree of depression. He had not determined whether it was a case of cause and effect, but some of his experimental work had indicated that it might be. He attributed the good effect of such drugs as calomel to the fact that the free movements produced and diminished the excretion of the etherial sulphates.

Dr. C. A. Herter, of New York, read a paper entitled

the acid intoxication of diabetes and its relation to prognosis.

He spoke of the method of opposing the acids and bases as the best means of detecting the amount of acid in the urine. As a clinical help, the detection of the nitrogen of ammonia was of much value, but not absolutely reliable. He found that with the increase of organic acids, measured as oxybutyric acid, coma was imminent. Crotomic acid was always present, and there was an increase for days, weeks or even months before the onset of coma. Coma develops, if large amounts of oxybutyric acid persist, say quantities greater than 25 grammes per day. When the urine contains little or no trace of organic acids there is little prospect of coma, though other troubles may present themselves.

DR. E. P. JOSLIN, of Boston, Mass., reported a case of

METABOLISM IN DIABETIC COMA WITH SPECIAL REFERENCE TO ACID INTOXICATION.

He related a case of fatal diabetic coma, and gave a detailed account of the chemical analysis of the urine from day to day, with special reference to the varying amount of organic acids.

Dr. VAUGHAN said that we do not yet know what the poisonous agent is in these so-called acid intoxications, but that we certainly know it is not oxybutyric acid nor acetone. He referred to the dietetic treatment of diabetes, and said that experimental work seemed to indicate that abstention from carbohydrates and excessive nitrogenous feeding might often do much more harm than good.

DR. HERTER agreed with this view of feeding such patients, and said that while he was not committed to the nature of the acid in the blood, yet such evidence as exists points to the oxybutyric acids more strongly than to the amido acids.

EVENING SESSION.

The evening session of the association was something of a novelty in its history, in that it was given up entirely to demonstrations.

DR. CHAS. S. BOND, of Richmond, illustrated by stereopticon some features of photomicrography, and explained the method of constructing the apparatus best adapted to securing the most perfect results in this work.

DR. W. T. COUNCILMAN, of Boston, gave a very beautiful and very instructive demonstration, with the stereopticon, of the renal lesions in diphtheria.

DRS. FLEXNER and WELCH each exhibited a number of important pathological specimens.

SECOND DAY.

DRS. BARKER, NOVY and FLEXNER demonstrated the

STUDY OF BUBONIC PLAGUE BASED UPON THE OUTBREAK IN SAN FRANCISCO.

DR. BARKER opened the discussion with a consideration of the clinical aspects of plague, stating that it belonged to the group of septicemic infections or diseases in which the causative agent can in very susceptible individuals produce a general sepsis without local lesion, but which in more resistant individuals gives rise to a disease characterized by local reaction without general sepsis. The character of the epidemic in San Francisco was like that which has prevailed during the early stages of all other epidemics. Thirty-one cases were definitely proven to be plague, and 28 of these occurred among the Chinese. The ordinary cases of plague begin suddenly, usually with a chill, with fever that increases rapidly, but has a curve characterized by intermissions and irregularities; the patient is nauseated, severe nervous symptoms follow, and generally within twenty-four hours the bubo appears. The course of the disease is a continuous and progressive failure until death occurs between the fourth and sixth days. The bubo develops differently from that accompanying venereal affections. The size varies, being sometimes as large as one's fist and occasionally so small that it can not be discovered by inspection or palpation. Buboes are most frequent in the groin, next in the neck, and then in the axilla.

The two principal types of plague are the bubonic and pneumonic forms; and a primary skin plague can probably be distinguished with a local lesion in the form of a carbuncle. In addition to these there is the plague septicemia, which may be divided into primary and secondary forms clinically. By the first is meant a septicemia produced by the entrance of the bacillus into the blood without the development of a bubo. In the secondary form there is a flooding of the blood by the plague bacillus, causing early death. In the early days of an epidemic, and again toward its close, there are usually found a number of mild cases, the patients not being sick enough to prevent their walking about. Such individuals are a source of great danger unless they can be isolated, for it has been proven that the urine and feces frequently contain the plague bacillus for as long as four or six weeks after apparent recovery. The pneumonic form of plague is characterized by a very bloody sputum containing immense numbers of the bacilli.

He referred to the great importance of recognizing the first case of plague, and said that he thought no disease was easier of diagnosis if one could take the proper steps. This should consist in a bacteriologic examination of the sputum, the blood, the splenic juices, and the bubo contents when present. Serum diagnosis is unreliable, except to show whether or not an individual has had the plague. He insisted upon the importance of regarding every case of fever occurring in a place where plague is suspected as being a case of plague, until it was proven to be something else, and furthermore the importance of believing at such times that every cadaver is one of plague until it has been bacteriologically examined.

As to treatment, he said that if he should contract the disease himself, he would promptly load up with the serum.

DR. NOVY considered the bacteriology of bubonic plague, reporting in detail the work done by the Commission in San Francisco, to prove the nature of the disease seen there.

(To be continued.)

LEPROSY IN THE UNITED STATES.— It is said that there are about 275 reported cases of leprosy in the United States. The number would undoubtedly be much larger were all cases promptly recognized and reported to the proper authorities. Of those reported nearly all are foreigners, a large proportion of them being among Italians in New Orleans. In general the disease appears to be spreading most rapidly in Louisiana.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 6, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

A MENACE TO BOSTON'S WATER SUPPLY.

FROM time to time there has been complaint of the danger of an overflow of sewage from the city of Marlboro into the general supply system of Boston. This danger, which exists at all times, is very materially increased by the excessive rainfall and accompanying freshets of the spring months. Owing to the exceptional amount of rain this year, the danger of pollution is greater than ever before, and it has become imperative that protective measures be adopted. It is said to be the opinion of the Metropolitan Water Board that the difficulty is due to a defect in the Marlboro sewage system. Under ordinary conditions the sewers are sufficient for the needs of the city, but they become inadequate when any unusual demand is made upon them, as, for example, during the heavy spring rains. As a consequence, a large amount of surface water has been introduced into the sewers, with the natural result that an overflow of surface water, mingled with filth, has occurred into the lowlands and into the Marlboro Brook filter beds, which are not constructed for the extra demand thereby put upon them. Impurities are apt to get into the Sudbury basin, and thence through water pipes to Boston. It is this state of affairs that is now demanding some radical solution. Negotiations are reported to be now under consideration, which have not yet been made public. It is apparent that the matter is of very vital importance to the health of the city, and, if the above statements are true to the facts, may prove a serious menace, unless the properly constituted authorities are immediately forced to act. A possible repetition of the experience with typhoid fever through which New Haven has just been passing should hasten action still more. If there is any one thing health officials should guard with the most unremitting care, it is the absolute purity of a city's water supply. Because the same conditions have prevailed for a number of years is absolutely no reason why any further delay should occur in remedying an evil which is so clearly remediable as this one appears to be. Moreover, the Boston Water Board early adopted the policy of encouraging the construction of works for the disposal of the sewage from such places. At Marlboro works were projected for disposing of the sewage within the watershed, and were changed so as to convey it a longer distance to a suitable place outside the watershed, and Boston paid $62,000 towards the expense.

A ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

IT is announced that John D. Rockefeller has given the sum of $200,000 for the foundation of what is to be known as the Rockefeller Institute for Medical Research. It is the object of the institute to maintain what is practically equivalent to scholarships in colleges where medical research is carried on, to enable those engaged in pathological, bacteriological, and other scientific work of the kind, to carry on their investigations with more adequate financial support. Dr. T. Mitchell Prudden, professor of pathology in the Medical Department of Columbia University, who has just been elected vice president of the Board of Directors of the Rockefeller Institute, while asserting that it was as yet too early to make a detailed announcement of what will be done even in the immediate future, has given out the following general statement: "This $200,000 will enable us to go ahead with work that is highly important for the general welfare. Much work of an investigating kind has already been done in the colleges, but their principal object, after all, is to teach. The fund given by Mr. Rockefeller will make it possible for men who want to devote themselves to special lines of medical research to do so without being hampered in any way. The possibilities are, of course, large . . . . This fund will provide a means for scientific research into the causes of various diseases, and it is hoped that both interesting and valuable results will follow."

Dr. William H. Welch, of Johns Hopkins Medical School, who will be the president of the Board of Directors, is reported as saying: "Medical research along the lines of preventive agencies is one of the most important matters occupying the minds of medical men today, and the study of antitoxins, serums and other preventives is now being pursued with zeal everywhere. It is to aid this research that Mr. Rockefeller has made his gift."

As we understand the terms of this gift, no money will be spent on buildings, but small sala-

ries will be paid a large number of investigators working in already established laboratories. For instance, in this neighborhood we understand there will be one such in connection with Dr. Councilman's department at the Harvard Medical School, and one in connection with Dr. Theobald Smith's department at the Bussey Institute. There are to be certain directors at large of the Institute, but the detailed investigations will be under the direct supervision of the heads of the various laboratories.

We understand Mr. Rockefeller's present proposition is to give $10,000 a year for twenty years. It is not to be doubted that successful and satisfactory results of a positive character may lead to generous modifications of the present provisions. It seems to be a wise and hopeful scheme, conceived on a judicious basis and possessing large possibilities.

DIPHTHERIA AND BOARDS OF HEALTH.

THE experience of a citizen of a neighboring city with regard to diphtheria and the regulations of the Board of Health is worthy of comment from various points of view. The victim of the affair expresses his feelings graphically, and yet fairly, in a daily paper. The circumstances appear, in brief, to have been as follows: A man is taken ill with a somewhat insignificant sore throat, a physician is summoned, who makes light of the situation clinically but suggests that a culture be taken. This is done by the appointed authorities in the Board of Health, with the result that the diphtheria bacilli are found. According to law, the house where the patient lived is placarded, and he himself is quarantined. In the meantime the sore throat has wholly disappeared, and the patient feels perfectly well. Later cultures, however, remain positive, thereby rendering the person who harbored the bacilli a possible menace to others. Here is the dilemma, which clearly is likely to be looked at very differently by the laity and by the medical profession, whose duty it is to safeguard the public health, if necessary, at the expense of the individual. There is something to be said on both sides of such a question as this, which is likely to become more and more prominent as time goes on. The afflicted individual certainly is not to be blamed for an attitude which to him and to people at large is a wholly natural one. It will always be difficult to induce people to believe that their physical feelings are not a just criterion of their condition; hence, although we may not wholly agree with his conclusions, we can at least sympathize with a man who, so far as his standards go, is well, in spite of scientific evidence to the contrary. The complainant in the instance before us writes: "Of course I know, everyone knows, that culture taking is productive of most beneficial results. It assists the diagnostician and safeguards the public at large. But should it not be applied with some reasonable discrimination? At present, in Cambridge at least, a person's liberty is placed in the discretion of one man, who is privileged to act in the most arbitrary manner and from whose decision there is no appeal. Who, after he has once played the monkey in a farce like this, will ever allow a physician to take another culture from his throat, or if he does get one will ever let him live to lug it away?"

Undoubtedly, if such cases as this were to be often repeated, they would lead to an evasion of the law, a difficulty with which boards of health always have to contend in greater or less degree. It is highly desirable that such evasion should be avoided; but we confess we have not forthwith a means to suggest, which will do justice, both to the individual and to society at large.

From the point of view of the Board of Health, we need hardly say that in the present state of our knowledge its action was absolutely justified. It acted as boards of health must always act, regardless of the individual, and with sole regard to the public at large. The solution of such a dilemma as this must ultimately lie in more knowledge of the virulence of the bacilli under varying condition, a subject upon which we are quite aware an enormous amount of work has already been done, but upon which still more remains to be accomplished. In the meantime, we must regret the occasional inconvenience to which the individual may be put, but not thereby neglect for a moment the large question at issue.

MEDICAL NOTES.

PRESIDENT OF JOHNS HOPKINS UNIVERSITY.— Prof. Ira C. Remsen has been elected president of Johns Hopkins University to succeed Mr. Gilman. He has been connected with that university as professor of chemistry since its foundation in 1876. He is 55 years of age and is a graduate of the College of Physicians and Surgeons of New York.

NORTH CAROLINA REFUSES A CHARTER TO A SO-CALLED SCIENCE COLLEGE.— It is reported that North Carolina, through its Secretary of State, has refused to charter a new college of science and mental healing, on the ground that its purposes conflict with the law governing the issuance of licenses to practise medicine.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 5, 1901, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: diphtheria 77, scarlatina 34, measles 273, typhoid fever 11, smallpox 1.

Precautions against Smallpox in Quincy, Mass.— The recent discovery of a case of smallpox in Quincy has led to the careful quarantining of several suspected houses. A cottage will be built on the almshouse grounds by the Board of Health for the accommodation of several families which are known to have been exposed.

NEW YORK.

The New Mount Sinai Hospital.— The corner-stone of the new Mount Sinai Hospital, which is to occupy the block between Fifth and Madison Avenues and 100th and 101st Streets, was laid on May 22d in the presence of over three thousand persons. It bears the inscription, "Mount Sinai Hospital, Beth Chauline, Incorporated 5612–1852." Addresses were made by Isaac Stern, chairman of the building committee, Randolph Guggenheimer, president of the Municipal Council, Seth Low, president of Columbia University, Isaac Wallach, president of Mount Sinai Hospital, Dr. Abraham Jacobi, president of the Medical Board, and Edward Lauterbach, Esq. In the course of his remarks Mr. Low said: "I count it not the least of the hospital's services that none is asked whether he be Jew or Gentile, Catholic or Protestant; it is enough that he is a man"; and Mr. Lauterbach made the statement that the records show that Mount Sinai has cared for more free patients, considering its size and capacity, with a higher record of medical and surgical service and ability, than any other hospital in the United States.

Modified Hippocratic Oath for Nurses.— The graduating exercises of the training-school for nurses at the City Hospital, Blackwell's Island, were held on June 1st. There were fifty-two graduates. On this occasion an innovation was made which met with hearty approval, and which will no doubt be adopted in other schools of the kind, in the administration of a modified Hippocratic oath to the class. It was administered by Mrs. Cadwalader Jones, chairmain of the Advisory Board, and two of its clauses were the following: "That you will be loyal to the physicians under whom you serve, as a good soldier is loyal to his officers." "That whatsoever you shall see or hear of the lives of men and women, whether they be your patients or members of their households, you will keep inviolably secret, whether you are in other households or among your own friends."

Payment of Life Insurance Premium while in Quarantine. — An interesting case regarding life insurance premiums and quarantine by the health authorities is reported from Geneva, N. Y. A female patient, who had been quarantined for about six weeks on account of smallpox, notified the board of health that her life insurance policy was likely to lapse because she was unable, on account of her enforced seclusion, to procure the money to keep it up, and demanded that the sum due should be paid by the board. President McGuire decided that the board had a right to pay and had better do so, on the ground that if the policy lapsed on account of the quarantine regulations and the woman died, the city might be called upon to make good the amount of the policy.

The Central Park Ostrich not Tuberculous.— The death of an ostrich in the Central Park menagerie, apparently from tuberculosis, has excited considerable attention, from the fact that it has always been maintained that birds are never subject to this disease. On this account Dr. Edwin Reynolds, chief physician to the Brooklyn Home for Consumptives, was asked to make an autopsy. He reports that death was due, not to tuberculosis, but to abscess and inflammation of the left lung, caused by the lodgment of a kernel of corn in one of the bronchial tubes. Not a single tubercle baccillus was found in the lungs; but in order to test the matter finally, Dr. Reynolds proposes to inoculate healthy guinea pigs with serum from the diseased organ.

Difficulties of the Kneipp Cure.— It is somewhat hazardous to carry out the Kneipp cure in the vicinity of Fishkill, N. Y. Recently an invalid who, it seems, had received a course of instruction at a Kneipp establishment at Poughkeepsie, was seen walking along the roadside without shoes or stockings, and as it was supposed on this account that he was a patient escaped from the neighboring State Hospital for Insane Criminals at Matteawan, he was, notwithstanding his protests, arrested and subjected to considerable inconvenience before he succeeded in convincing the authorities of the mistake that had been made. It appears that there is a standing reward of $25 in the community for the capture of any inmate of the institution who escapes.

Twelve Thousand Dollars for the Brooklyn Home for Consumptives.— A decision has been handed down by Surrogate Abbott, in Brooklyn, admitting to probate the will of Miss Maria Sprague Meeker, which left her residuary estate, amounting to about $12,000 to the Hospital for Breadwinners, provided the latter was incorporated at the time of her death. If it was not incorporated at this time the money was to go to the Brooklyn Home for Consumptives. The Hospital for Breadwinners was not incorporated at the time of the death of the testatrix, and

the Surrogate decides that the residuary estate goes to the Home for Consumptives. The will was contested by two nieces of the deceased.

DEDICATION OF BUILDINGS AT THE LOOMIS SANITARIUM.— The Church of St. Luke the Beloved Physician, a beautiful chapel at the Loomis Sanitarium for Consumptives at Liberty, N. Y., erected by Mrs. Alfred L. Loomis in memory of her husband, was dedicated on May 27th by Bishop Potter. Other buildings at the sanitarium dedicated on the same day were: The new administration building, the gift of J. Pierpont Morgan; a handsome library, the gift of Mrs. James H. Aldrich, in memory of her father, Mr. Edson; and an annex for the accommodation of charity patients. The graduating exercises of the 1901 class of trained nurses was also a feature of the occasion.

ANOTHER SANITARIUM FOR TUBERCULOSIS.— The new buildings of the Country Sanitarium for Consumptives, a special department of the Montefiore Hospital for Chronic Diseases, situated near Bedford, Westchester County, were formally opened on Memorial Day with addresses by Bishop Potter, Vice President Roosevelt, Jacob H. Schiff, president of the Montefiore Hospital, Oscar S. Strauss, lately U. S. Minister to Turkey, Dr. Alfred Meyer, physician-in-chief of the sanitarium, and others. The buildings now completed will accommodate 150 patients, and it is proposed to enlarge them to a capacity of at least 500.

CONSECRATION OF A CONVALESCENT HOME.— On May 27th Archbishop Corrigan consecrated the Convalescents' Home at Tuckahoe, Westchester County, N. Y., a commodious building with ample grounds, presented by Adrian Iselin and his daughter. It is designed as a place of recuperation for patients discharged from the New York hospitals.

SMALLPOX IN BELLEVUE HOSPITAL.— It is reported that within ten days no less than twelve persons suffering from smallpox have presented themselves at the outdoor department of Bellevue Hospital.

Miscellany.

THE BLESSINGS OF CHARITY.

WE have received the following appeal addressed to a confrère in a neighboring city, which is worthy of reproduction:

DEAR SIR:

The liberty & equality of this country, where it is no diversity bettween creed & nationality, are encouraging me to write the following lines: my bad state is indescribable, but very easy to imagine my position; when my small earned wages must be spent for Dr. & medecine. and nothing can be left to satisfy the stomachs of my poor four children. To send this patient to hospital is impossible, firstly she cannot be seperated from the children, secondly I have nobody to take care of them when she ll be in hospital. Therefor by the name of humanity, the divine faculty, I request you to send a Dr to my place if possible as it is done in some other cities. By doing the above you will save the life of four children who are suffering limitless.

Your obedient servant,

Following the above, the benevolent physician received this message:

Discerning your charitable carre by visiting my humble house where a poor helpless woman is confined to her cot, with poor four children, whose only hope is only in you, I encourage myself to ask your honor to call today as she feels worse.

Your humble servant,

Obituary.

ALLEN M. SUMNER, M.D.

DR. ALLEN M. SUMNER died at his home in Boston May 25th, at the age of fifty-seven years. He was born January 31, 1844, and had been a resident of Boston most of his life. Receiving his early education in the public schools, Dr. Sumner entered the Lawrence Scientific School, Cambridge, where he received the degree of S.B.; later he received the degree of M.D. from the Harvard Medical School. He then studied for several years in London, Paris and Vienna. Returning to America he entered upon the practice of medicine in Boston, where he continued to reside up to the time of his death. He was for many years a visiting physician at the City Hospital, a position from which he resigned about three years ago. For twenty-nine years he was connected with St. Luke's Home for Convalescents, and at the time of his death was senior physician on the consulting staff. He was a conscientious and skilful practitioner and a physician of wide experience, which his long service at the City Hospital did much to foster and increase. A wife and two children survive him.

RESOLUTION ON THE DEATH OF DR. SUMNER.

Resolved, That in the death of Dr. Allen M. Sumner on May 25, 1901, St. Luke's Home for Convalescents lost a faithful adviser and a loyal friend. His services covered a period of twenty-nine years: from 1872 to 1878 on the active staff, and from 1878 to 1901 on the consulting staff, the last seven years he being the senior physician of the Home. Dr. Sumner was always ready with timely counsel and practical assistance to further the welfare of the patients, and his careful attention to the duties of his office served to enlist the regard and respect of those associated with him in the work of St. Luke's Home for Convalescents, Boston.

Resolved, That the Trustees and Medical Staff extend to the family their sincere sympathy in their very great affliction.

WALLACE H. HAM, *Secretary*.

GEORGE S. OSBORNE, M.D.

DR. GEORGE STERNE OSBORNE of Salem, Mass., died at his home, May 25th, at the age of 62, of heart failure. He was educated in the Salem schools, and was fitted there for Harvard, which he entered in 1856. He did not complete the four years' course, but in 1859 entered the Harvard Medical School, from which he graduated. On July 8, 1862, he enlisted in the First Massachusetts Cavalry, and became assistant surgeon, with the rank of lieutenant, March 17, 1863. On December 30, 1863, he was promoted to major and made surgeon of the Fifth Massachusetts Cavalry, but

resigned May 7, 1864, on account of illness. He returned to the service later. He spent the next two years studying in Vienna and Paris. On returning to this country from this period of study he began practice in Peabody. He continued until 1894, building up a large and successful practice.

He was a member of various social and professional organizations, and a man who greatly endeared himself, both professionally and socially, to a wide circle.

Correspondence.

DISGRACEFUL AND ANNOYING MEDICAL ADVERTISEMENTS IN CURRENT MAGAZINES AND NEWSPAPERS.

NEW HAVEN, CONN., May 18, 1901.

MR. EDITOR: — With all our medical practice acts and efforts at pure medical journalism, it seems strange that no tether can be placed upon the quack rampant on the field of magazine and newspaper advertising pages. These gentlemen assure you that all kinds of diseases "can be cured while you wait, consultation free." "Let us send you a bottle." "Keep your hats on, gentlemen; it will all be over in a minute." Trash of this nature obstructs our view in current periodicals. One distinguished gentleman assures the public that he abolishes varicocele and appends his beautiful physiognomy posed for the occasion in half-tone, with a page of vituperated slush about what he knows he cannot do. "Ideal sight." "Are you deaf? Put the electric battery in a foot-tub (or anything convenient) and watch it," with a lucid illustration of an impossibility. Blood cures, body braces, hair on your face, crowd upon one another with the energy of horses at the race-track.

These vacuous fellows keep up a "continuous performance" and increase yearly in our best periodicals, and we either can not, will not, or dare not, try to stop it. The medical profession can say, with truth, that quackery is beneath its contempt. This is true; but the fact remains, that these magazines fall into the hands of innocent young people. Curiosity, a human trait, is awakened.

Then questions will be asked about matters that they have no business even to hear of, least of all to mention. "Money talks." Vulgar as this expression may be, it is the root of all this blatant trash hurled in our faces daily by the squawking quack.

If some form of legislation could be enacted to curtail these gentlemen "who will let you try it for yourself," we might have less of their warblings, if not, in time, total extinction of the nuisance.

Very truly yours,

G. TOTTEN-MCMASTER, M.D.

SUBSCRIPTIONS FOR MONUMENT TO PROFESSOR OLLIER.

1729 CHESTNUT STREET, PHILADELPHIA,
June 3, 1901.

MR. EDITOR: —Some time since you kindly published an appeal of a committee soliciting subscriptions for a monument to the late Professor Ollier in Lyons. As treasurer of the committee, I beg that you will publish this letter in your journal in order to inform the profession that I have received the sum of $649 from 103 subscribers. I have forwarded the same, less $4.60 for postage, printing, etc., to Dr. G. Mondan, 27 Rue Jarente, Lyons, France.

Yours very truly,

W. W. KEEN, M.D., *Chairman.*

Deaths reported 2,420; under five years of age 691; principal infectious diseases (smallpox, measles, scarlet fever, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 594, acute lung diseases 313, consumption 318, scarlet fever 45, influenza 3, erysipelas 10, typhoid fever 20, whooping cough 21, measles 16, cerebro-spinal meningitis 11, smallpox 13.

From whooping cough, New York 7, Philadelphia 9, Baltimore 2, Boston 1, Cambridge 2. From cerebro-spinal

meningitis. New York 4, Philadelphia 2, Baltimore 1, Boston 3, Pittsfield 1. From scarlet fever, New York 32, Philadelphia 6, Baltimore 1, Boston 1, Worcester 2, Lynn, Brockton and Newton 1 each. From typhoid fever, New York 5, Philadelphia 9, Baltimore 2, Boston, Lowell, Taunton and Waltham 1 each. From erysipelas, New York 7, Philadelphia 1, Boston 2. From smallpox, New York 13.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,463,187 for the week ending May 11th, the death rate was 16.5. Deaths reported, 3,635: acute diseases of the respiratory organs (London), 237, whooping cough 118, diphtheria 63, measles 90, fever 25, scarlet fever 38.

The death rate ranged from 7.7, in Croydon, to 22.3, in Brighton; Birkenhead 12.7, Birmingham 18.9, Blackburn 17.1, Bolton 15.8, Bradford 17.3, Bristol 17.4, Burnley 13.9, Cardiff 14.2, Derby 15.2, Gateshead 13.2, Halifax 15.9, Huddersfield 14.3, Hull 19.5, Leeds 16.1, Leicester 14.2, Liverpool 18.5, London 15.9, Manchester 20.7, Newcastle-on-Tyne 17.2, Norwich 17.2, Nottingham 15.6, Oldham 18.6, Plymouth 11.6, Portsmouth 17.0, Preston 14.3, Salford 18.4, Sheffield 16.5, Sunderland 16.6, Swansea 20.4, West Ham 14.9, Wolverhampton 16.0.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, WEEK ENDING MAY 25, 1901.

R. M. KENNEDY, passed assistant surgeon. Ordered home via public conveyance.

M. V. STONE, assistant surgeon. Detached from "Buffalo" and ordered home to wait orders.

C. H. DELANCY, assistant surgeon. Detached from "Bancroft" and ordered to the "Buffalo."

F. M. FURLONG, assistant surgeon. Ordered home via public conveyance.

D. B. KERR, assistant surgeon. Ordered home via public conveyance.

E. J. GROW, assistant surgeon. Ordered home via public conveyance.

A. G. GRUNWELL, assistant surgeon. Ordered home via public conveyance.

D. G. BEEBE, assistant surgeon. Ordered home via public conveyance.

C. D. LANGHORNE, assistant surgeon. Ordered home via public conveyance.

J. STEPP, assistant surgeon. Detached from the "Castine" and ordered to the "Isla de Luzon."

E. J. GROW, assistant surgeon. Detached from the "Isla de Luzon" and ordered to the "Castine."

E. THOMPSON, assistant surgeon. Detached from the "Solace" and ordered to the "Petrel."

R. W. PLUMMER, assistant surgeon. Detached from the "Petrel" and ordered to the "Nashville."

F. M. Furlong, assistant surgeon. Ordered detached from the "Brutus," and ordering him forward to Guam, L. I.

RECENT DEATHS.

DR. JOHN E. COMFORT, a prominent physician in the Borough of the Bronx, New York, died on May 29th. He was born in St. Louis, Mo., October 6, 1837, and was graduated from the Albany Medical College in 1864. During the latter part of the Civil War he served as assistant surgeon of the Sixtieth Regiment New York Volunteers. Ever since the war he had practiced in that portion of Westchester County which a number of years ago was annexed to the City of New York and is now known as the Bronx, and for twelve years he was an inspector of the New York Board of Health.

DR. JOHN L. FEENY, Sanitary Superintendent of the Borough of Richmond, New York, died after an extended illness, at his home at Stapleton, Staten Island, on May 31st. He was born in 1845 and was graduated from the Medical Department of the University of the City of New York in 1866. After serving for three years as house physician at the Seaman's Retreat Hospital, on Staten Island, he commenced private practice at Stapleton. From 1870 until the recent consolidation of the Boroughs composing the Greater City of New York, he was surgeon to the police department of Richmond County, and during the greater part of this time was also health officer of the towns of Edgewater and Middletown.

BOOKS AND PAMPHLETS RECEIVED.

Eighteenth Report of the State Board of Health of Wisconsin, September 30, 1900. Madison, Wis., 1901.

Metropolitan Water Board. Sixth Annual Report. January 1, 1901. Boston: Wright & Potter Printing Co. 1901.

Klinische Versuche mit dem Fleischsafte "Puro." Von Dr. Jos. Vesely, Assistent. Sonder-Abdruck aus der Prager Med. Wochenschrift. 1901.

Syphilis as a Non-Venereal Disease. With a Plea for the Legal Control of Syphilis. By L. Duncan Bulkley, A.M., M.D., New York City. Reprint. 1901.

Circular on Tropical Diseases. Number I. Chief Surgeon's Office, Headquarters Division of the Philippines, Manila, P. I. Reprint. 1901.

Bulletin de l'académie Royale de Médecine de Belgique. Bruxelles: Hayez, Imprimeur de l'académie royale de médecine de belgique, Rue de Louvain, 112. 1901.

Proceedings of the Philadelphia County Medical Society. Report and Exhibition of a Case of Dermographism. By Jay F. Schamberg, M.D. Vol. XXII. Reprint. 1901.

The Extra Pharmacopœia. By William Martindale, F.L.S., F.C.S., and W. Wynn Westcott, M.B. (Lond.) D.P.H. Tenth edition. London: H. K. Lewis. 1901.

A Treatise on the General Principles and Special Applications of Hematology. By James Ewing, M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1901.

How to Cook for the Sick and Convalescent. Arranged for the Physician, Trained Nurse and Home Use. By Helena V. Sachse. Philadelphia: J. B. Lippincott Company. 1901.

Transactions of the Twenty-second Annual Meeting of the American Laryngological Association. Held in the City of Washington, D. C., May 1, 2 and 3, 1900. New York: Carey Printing Co. 1901.

Transactions of the Obstetrical Society of London. Vol. XLIII, for the Year 1901. Edited by Herbert R. Spencer, M.D., Senior Secretary, and Alban Doran, F.R.C.S. Illustrated. Published by the Society.

An Inquiry into the Existence of Autochthonous Malaria in Buffalo and its Environs. Preliminary Report on Species of Mosquitoes and Blood Examinations. With map. By Irving P. Lyon, M.D., and Alfred B. Wright, Buffalo, N. Y. Reprint. 1900.

Induction Coils. How to Make, Use and Repair Them. Including Ruhmkorff, Tesla and Medical Coils, Röentgen, Radiography, etc. By H. S. Norris (Norman H. Schneider). Second edition, revised and enlarged. New York and London: Spon & Chamberlain. 1901.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. By James Nevins Hyde, A.M., M.D., and Frank Hugh Montgomery, M.D. Sixth and revised edition. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1901.

Primary Echinococcus Cysts of the Pleura. Report of a Case of Primary Exogenous Echinococcus Cysts of the Pleura, Showing Hyaline Degeneration of the Cuticle without Lamellation, with Notes from the Literature. By Charles Cary, M.D., and Irving P. Lyon, M.D., Buffalo, N. Y. Reprint. 1900.

A System of Physiologic Therapeutics. A Practical Exposition of the Methods, Other than Drug-Giving, Useful in the Treatment of the Sick. Edited by Solomon Solis Cohen, A.M., M.D. Vol. II. Electrotherapy by George W. Jacoby, M.D. In two books. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1901.

The Occurrence of Malta Fever in Manila. By Richard P. Strong, M.D., Assistant Surgeon U. S. A., Director of the Army Medical Laboratory, Manila, and President of the Board appointed by the Secretary of War for the Investigation of Tropical Diseases in the Philippine Islands; and W. E. Musgrave, Hospital Steward U. S. A., Resident Pathologist to the First Reserve Hospital. Reprint. 1900.

Coincident Typhoid and Malarial Infection. Report of a Case and Review of the Literature, with a Discussion of the So-Called Typhomalarial Fever. By Irving Phillips Lyon, M.D. (Johns Hopkins), Buffalo, N. Y., Former House Medical Officer, Johns Hopkins Hospital, Baltimore; Clinical Pathologist to the New York State Pathological Laboratory of the University of Buffalo; Instructor of Clinical Medicine in the University of Buffalo. With charts. Reprint. 1900.

Address.

INTERNAL MEDICINE IN THE NINETEENTH CENTURY.[1]

BY N. S. DAVIS, JR., M.D., CHICAGO.

It is one of the duties of those who address you, as I do today, to review what has been newly discovered in the field of medicine or in some limited department of it. At this first meeting of the American Medical Association in the twentieth century, it seems most natural to review what has been accomplished in the last one hundred years. The time at my disposal is too brief to read to you a complete history of the achievements of this wonderful epoch, for more of genuine advancement has been made in medicine during it than during all the preceding centuries together. It is only possible for me to point out some of the reasons for the rapid development of medicine, to recall to your minds some of the most important discoveries and applications of them.

A century is not so long a time as we are apt to think. Our grandfathers were vigorous men, in the prime of life, when the nineteenth century was born. Yet changes so great that they seem miraculous have occurred since then. In 1800 this great country was a wilderness, unknown even to the inhabitants of the few straggling settlements upon the Atlantic coast. Our land contained no great cities. There was little travel from place to place. There were no steamboats nor railways; no telegraphs nor telephones. Information traveled slowly by packet ship, canal boat and stage coach. The discovery of the wonderful properties of the x-ray could not then have been flashed over the world in a day, and its genuineness and utility confirmed within a few weeks by experiments made simultaneously in all parts of the world, as did happen at the close of the century. Today all civilized peoples are so united that knowledge has become the common property of them all. In former epochs geniuses delved alone, inspired only by their own enthusiasm. Often it was many years before their discoveries became widely known or appreciated; and many more before another genius standing upon land already found ventured upon its exploration.

All this has been changed. Learning is not possessed by a few, but by many. In earlier epochs men of genius towered above their contemporaries in learning. Today thousands crowd about their shoulders, so much higher is the average of learning. All scientific workers are now linked together by the rapid dissemination of news, so that no matter in what part of the world they may be, they are kept conversant with what is being thought and done in every other part, and they are thereby inspired to greater mental efforts.

Knowledge is no longer isolated. It is cultivated in centers too numerous to count. Even in this new land universities with great libraries, finely-equipped laboratories, and corps of brilliant teachers and seekers after new knowledge, are found in every part of it. Medical societies have been organized in every state and city, and in many counties and towns. But at the beginning of the century there were only four medical schools in this country, and four state societies, organized for the advancement of medical knowledge.[2]

These changes have been effected chiefly by the rapidity of communication which has been established in all civilized lands and by the greater concentration of the people in large cities.

But it is not in the United States only that the population has increased and concentrated. In 1801 the total population of England and Wales was less than 9,000,000. Of this number more than half lived in the country. At the end of the nineteenth century the population of the same countries was more than 29,000,000, and only one-fifth of this number lived in rural districts. These figures attract our attention to the social changes which have occurred in all civilized lands — changes which have effected not only a greater diffusion of knowledge, but have also modified the conditions which produce and limit disease.

At the opening of the nineteenth century "Cullen's Practice of Physic," written late in the preceding century, was the standard text-book. A glance at its contents will give us the clearest conception of the state of medical knowledge at that time. In an edition of this work printed in New York City in 1806 I find no description of structural diseases of the heart; even as a complication of rheumatism, heart disease is not mentioned. A single page is devoted to nephritis, but in its description there is no mention of the chemic and microscopic changes in the urine, upon which we depend to recognize it and to distinguish its forms. The affections of the respiratory organs were described with similar crudeness, under such chapter headings as "Of Catarrh," "Asthma," "Pneumonic Inflammation," "Peripneumonia Notha," and "Phthisis Pulmonalis," but the catarrhal inflammations of the nose, pharynx, trachea and bronchi were not differentiated from one another, nor were catarrhal and croupous pneumonia, brown induration, hypostatic congestion and edema of the lungs described.

The hypothetical explanation of diseases and their causes which prevailed at that time is well illustrated by the conclusion reached by Noah Webster, who in his "History of Epidemics and Pestilential Diseases" writes that typhus and nervous fever are due to "conversion of the perspirable fluids of the body into septic matter."

Nothing will help so much to make clear the progress made in medicine in the last century as to compare the resources at the disposal of physicians of our day with those commanded by our grandparents. At the opening of the nineteenth century medical men knew nothing of the clinical

[1] Annual oration in medicine, delivered at the fifty-second annual meeting of the American Medical Association, held at St. Paul, Minn., June 4-7, 1901.

[2] The colleges were medical departments of Pennsylvania, Columbia, Harvard and Dartmouth (founded 1797). The societies were New Jersey (1766), Massachusetts (1781), Connecticut and New Hampshire (1791).

thermometer, of percussion, auscultation, uranalysis, clinical microscopy, laryngoscopy, ophthalmoscopy, of the sphygmograph, or Röntgen rays.

It was not until the year 1808 that Corvisart spread widely a knowledge of percussion as a means of discovering the physical status of the viscera, although the work of Avenbrugger which he translated, and which was the original description of percussion, had been published nearly fifty years before. The work of Avenbrugger and Corvisart was supplemented in 1819, when Laennec published the result of his labor with the stethoscope which he invented four years earlier. From this time dates our clinical knowledge of diseases of the lungs and heart.

In 1827 Bright pointed out the relationship of albuminuria, dropsy and diseases of the kidneys. At this point clinical chemistry may be said to begin.

At the beginning of the nineteenth century compound microscopes were almost usless, for the images which their lenses made were so distorted and colored that they could not be properly interpreted. In 1812 Dr. William Hyde Wolleston combined two plano-convex lenses so as to correct the spherical aberration which a single double-convex lens produces; and nearly twenty years later Joseph Jackson Lister discovered the utility of combining lenses of crown and flint glass in order to produce an image in the microscope relatively free from distortions and fringes of color. The more recent invention of the oil immersion lens has made bacteriology possible, and has solved many of the problems of infectious diseases which puzzled even our fathers in the fifties and sixties.

The dependence of medicine upon ancillary sciences is well illustrated by the sudden birth and rapid development of new branches of medical knowledge which are dependent on the perfection of the microscope.

This instrument has made histology, embryology, modern pathology and bacteriology a possibility. These departments of science are altogether products of the last century.

It was at the beginning of the century that Bichot divided the structures of the body into what he called "tissues," and showed that there were only a few of them. It is surprising that the great anatomists before him did not make the same discovery.

As modern anatomy has been dependent upon the microscope in order to explain structures, so physiology has been dependent upon experiments on living animals to explain function. It is true that in earlier epochs at considerable intervals of time experiments upon living animals were made, notably by Harvey when he studied the circulation of the blood, but they were never made systematically until the discovery of anesthesia in the nineteenth century made them painless. No wonder, therefore, that the explanations made by physiologists in 1800 seem to us extremely crude. Haller, for instance, whose printed lectures formed the text-book of most students at that time, thus describes the nature of blood: "Hydrostatical experiments demonstrate in the blood first a kind of volatile vapor or exhalation which immediately and continually flies off from the warm juice with a sort of fetid odor coming betwixt that of sweat and urine. This vapor being catched and condensed in proper vessels, appears of a watery nature, joined with a small tincture of an alkaline disposition."

A few pages further on what he says of the blood gives us an idea both of the state of physiologic and pathologic knowledge at that time: "For the blood in a sound, healthy state, not injured by putrefaction or too violent a degree of heat, is neither alkaline nor acid, but mild and gelatinous, and a little saltish to the taste; yet in some diseases it is sharp enough and comes near to a state of putrefaction; as for instance in the scurvy, when it corrodes through its containing vessels, and in those who have ascites or dropsy whose waters are often much of an alkaline and corroding nature."

At the close of the eighteenth century the part which gland cells play in forming secretions was not comprehended. It was believed that "the albuminous or hardening juices are separated almost anywhere from the arteries themselves, into continuous excretory canals, with any intermediate organ or machine betwixt them." It was believed that all excretions existed primarily in the blood.

The physiologists of this period appreciated the importance of the lungs and the act of respiration, but their exact use they did not comprehend. Haller enumerates several possible functions which they might perform, yet he did not feel sure that any one of them were the real ones. For instance, he says: "Our blood acquires its heat principally in the lungs; for that all animals which have lungs and two ventricles in the heart have the heat of their blood commonly twice that of the atmosphere. But does not this arise from the alternate extension and contraction, relaxation and compression of the pulmonary vessels by which the solid parts of the blood are perpetually rubbed together and closely compressed in the attrition that is made during expiration, as it is more rapidly moved and ground together during inspiration."

Our forefathers one hundred years ago often endeavored to hide their ignorance in long names and resounding phrases,—a common practice, indeed, in all times and not wanting today; for how much ignorance will our successors find hidden in words now so commonly used as are metabolism and autointoxication.

Pathology as a distinct department of scientific medicine originated in the nineteenth century. It was not until 1860 that Rudolf Virchow demonstrated conclusively his famous dictum: "*Omnis cellula e cellula.*" His studies of cells in disease laid the foundation and did much to rear the superstructure of cellular pathology. So rapidly has a knowledge of this subject grown that we can unhesitatingly say that we now possess very accurate and detailed information as to the anatomical

changes which disease effects. The insight of physicians was so greatly extended into the nature of morbid processes by these pathologic studies that enthusiastic devotees of them felt that the application of the microscope to the study of disease would dispel its mysteries. Increasing information, however, soon demonstrated the limitations which exist as to knowledge derivable from a study of morbid anatomy. Most of us remember how, soon after the birth of bacteriology, it was also hoped that from it at least we would learn the true essence of disease. But we know now that in most ailments after the bacteriologist has discovered the offending micro-organism the chemist must help us, for it is usually a product of its growth, not its physical presence in the tissues, that causes disease.

The production of disease by parasites imbedded in the tissues of the human body was suspected from early times, but was not demonstrated until the end of the first third of the nineteenth century, when James Paget, then a medical student, found unusual nodules in the muscles of a man whom he was dissecting. These Richard Owen demonstrated to be the cocoon of a minute animal which he called *trichina spiralis*. In 1847 Dr. Joseph Leidy of Philadelphia found them also in pork, and soon thereafter it was shown in Germany that men could become infected by eating pork containing trichina, and that in consequence there developed in them a definite train of symptoms.

In 1837 Latour in France and Schwann in Germany almost simultaneously propounded the view that fermentation and putrefaction are due to the growth of micro-organisms. Liebig, with all the weight of his authority, antagonized this belief in a "vitalistic" explanation of these phenomena. Pasteur undertook to settle the dispute by methods of research, which proved to be the foundation of a new department of science — bacteriology. The results of his experiments were published between 1857 and 1869. He proved that without micro-organisms there could be no fermentation, no putrefaction or decay. These studies prompted many investigators to attempt to demonstrate the suspected relationship of micro-organisms to disease. In 1863 Devaine succeeded in showing that the organisms seen by him in 1850 in the blood of animals which had died of anthrax, were its cause. This, as some of those before me will remember, aroused a storm of controversy which was not settled finally until after my own student days.

Formerly, such vague terms as "miasm," "humor" and "virus" were used to explain the communicability of contagious diseases, but they have had to be discarded or to be newly defined by the bacteriologist. It was in the sixties that Lister made his studies upon the relationship of micro-organisms to wound infection. The brilliant revolutionary results of those studies are too well known to you to require elaboration; besides they belong to the history of the nineteenth-century surgery rather than to the history of internal medicine. They were, however, so important in settling the relationship of invisible parasites and diseases that they must be mentioned.

It was at this time, too, that Pasteur and Tyndall finally settled the controversy over spontaneous generation, which had raged from time immemorial. The world at last felt convinced that even micro-organisms could not exist where an antecedent organism had not been.

It is needless to recapitulate the long list of discoveries rapidly made from this time onward of the causes of infectious diseases, by such men as Koch, Klebs, Loeffler, Fraenkel, Laveran, and many others.

Although medical men have been incited to search for the causes of disease in order that they might understand their nature better and therefore be able to treat them better, such studies naturally led more directly to the prevention than to the cure of disease. That is why the recent epoch-making bacteriological discoveries have greatly stimulated the study of preventive medicine. It is true that the prevention of disease has engaged the attention of medical men and statesmen since the earliest times, but the subject was not studied systematically before the last century.

Hygiene as a separate department of medicine, with a literature of its own, was created only in the nineteenth century.

While in the eighteenth century much was done to improve the hygienic state of individuals, and as a result there began before its close to be a reduction in the mortality rate, which has continued up to the present time, public hygiene or attempts to prevent the spread of disease by state and civic interference, was not fairly established until very recently. Even today small communities have no health officers or sanitary inspectors, and few regulations which are intended either to inform the people as to the relative healthfulness of towns and hamlets, or by which the spread of disease is to be lessened. These facts show how new and undeveloped as yet the field of public hygiene is. The mortality statistics which have been gathered in cities since the middle of the last century make it possible to point out which among them are the healthiest, and which diseases are the most destructive. It is to be hoped that these statistics in the future will be supplemented by reports of the kinds and amount of illness, whether fatal or not, that may exist in a given place.

The knowledge recently acquired of infections and their spread has already been applied to their prevention. Such diseases as erysipelas, septicemia and tetanus no longer torment surgeons when they can make clean wounds. But as late as 1870 the first of these ailments was common in the hospitals of France. Puerperal fever is today as rare as it was common formerly. Typhus fever no longer exists in America, although not uncommon at the beginning of the last century.[3]

[3] Typhus forms an item in the mortality reports of Chicago (and other American cities) as late as 1886. This is probably because it was confused with typhoid. Not during the first quarter and rarely afterwards genuine typhus occurred in this country.

Indeed, it is rarely seen in any civilized country today. At the beginning of the nineteenth century smallpox was so common that few persons reached adult life without having had the disease, and the mortality from it in childhood was great. What is the status of this disease today? I venture to say there are many physicians in this audience who have never seen a case, and that a majority of them have not treated more than four or five cases during their whole professional experience. In the early days of this nation's history yellow fever spread to Philadelphia and New York, and provoked much discussion, for it was feared that it would prove as great a pest as cholera. A careful study of the disease and a consideration of the possibility of preventing it was referred to a committee of the New York Medical Society, which reported that yellow fever may be produced in any country by pestilential effluvia. How different is this conclusion from that of recent students of the subject, who assign to it a specific cause, which is transmitted from man to man by mosquitoes, who are its host.

Cholera has been brought to our shores several times in the last few years, but its spread has been prevented in each case. In Europe it has also been limited to comparatively small areas. Within a year the plague has been found in this country, in Great Britain and France, but has caused little alarm, so great is the confidence that it will be successfully suppressed. (Let us hope that this confidence is not misplaced.)

What has been accomplished during the last one hundred years by internal medicine the following statistics will show in part, although it must be remembered that mortality statistics gathered before the middle of the century are not reliable. It is estimated that in 1805 in New York City from 35 to 40 deaths occurred in every 1,000 inhabitants. During the last decade it has averaged 20 in 1,000, and has been as low as 19 in 1,000. In 1847 the mortality in London from zomotic diseases was 23.26%; during the last two decades 19% to 20%. In 1846 the deaths from consumption were 12.67%; now approximately 9%. The mortality from diseases of the respiratory organs has been reduced in the same time from more than 12% to about 7%, and the mortality from diseases of the digestive organs has diminished from about 6% to less than 5%. In Chicago the mortality rate has fallen, with small fluctuations, from 46 and 64 deaths per 1,000 inhabitants in the cholera years of 1852 and 1854, to 14 in 1898. The following diseases are among those in which the death-rate has fallen progressively: Cholera infantum, croup, diarrhea, diphtheria, dysentery, malaria, measles, scarlet fever and whooping cough. These are ailments the spread of which has been controlled either by isolation or by insuring the people purer food and water. Although the general mortality of Chicago, which is typical of the great cities of civilized countries, has improved, there are some diseases which are increasing in prevalence, notably nervous diseases, heart diseases, cancer, Bright's disease, bronchitis and pneumonia. To the discredit of my native city must it be said that the mortality from typhoid fever reached its highest point at the close of the century, during 1890, 1891 and 1892, although its cause and its mode of dissemination, as well as its prevention, were well known.

The general lowering of the death rate is due to the improved hygiene of communities. In what the improvement has consisted is best shown by recalling some of the conditions under which people lived in 1800. At that time few cities had an adequate public water supply. In London water could be delivered at any house three times a week by one of the water companies; but most households depended upon wells. The sewerage system was quite as imperfect. Outhouses and cesspools were attached to each dwelling. The conveyance of sewage from houses by water did not become general until well into the last century. Ventilation of buildings, and especially of public halls, had attracted attention before the nineteenth century; but the real causes of danger from bad ventilation were not appreciated until bacteriology disclosed them.

In 1800 streets were not paved, and rarely cleaned. The habits of the people as regards eating and drinking were bestial. Excessively large quantities of food were consumed by all who could provide it. Alcoholic beverages were universally drunk, and generally in immoderate quantities. No disgrace attached to drunkenness; and it was customary for a man to drink several bottles of wine at a sitting.

Those who compose this audience appreciate how much illness must have been caused by these habits, and how much the relative abstemiousness or temperance of today has lessened the percentage of disease.

Prevention of diseases is only possible when a knowledge of their causes, their mode of dissemination, and methods for their suppression is possessed by all the people. Medical men alone cannot stop their spread, nor will the making of laws do it. Only the intelligent co-operation of those who are ill and those who are well can accomplish it. It must not be expected, therefore, that as soon as the cause of a disease is discovered, that ailment can be suppressed. Time is required in which to educate all classes of people on that particular subject. Unfortunately, many persons are so obtuse that they will not believe in methods of prevention, even when the fullest demonstration of their success has been made. A notable instance of this is seen in the recent repeal of laws in England which made vaccination compulsory. The ease with which drinking water may become contaminated, and the danger to health from contamination, is not even now appreciated by the public. It is partly because such thorough knowledge is needed by the laymen that tuberculosis, diphtheria, pneumonia, typhoid fever and similar troubles have not been better controlled in the past. In order that in the twentieth century the fruits of the great discoveries of the last may be

gathered, all members of the medical profession must fit themselves to teach their patients what is known of disease and its prevention. Those who are especially adapted to do so must disseminate their knowledge by popular discourses and essays. When hygiene shall be regarded by all classes as necessary, and as much a matter of course as the use of the railroad, steamboat, the telegraph, telephone, and labor-saving machines, then, but not until then, striking results may be expected.

The wonderful, the revolutionary discoveries made by students of internal medicine during the nineteenth century are not always appreciated as they should be, for their results are often demonstrable only by statistics; and the dramatic rescue of individuals from certain death, which the surgeon at times accomplishes, unfortunately cannot be effected by the therapeutist. It is not in the nature of his art. Great progress, however, has been made in the use of medicines and remedial procedures. Good reasons can be given for their employment, and their mode of action can be explained. Empiricism no longer governs their use as it formerly did. The placing of therapeutics upon a scientific basis began in the last century, when the physiological effect of drugs was first demonstrated by experiments upon animals.

No field of medical research needs cultivation so much or is more certain to yield a rich harvest than therapeutics. It is surprising that we have not a larger volume of accurate knowledge of the effect of drugs than we do possess. Of late pharmacology has been neglected for studies which have temporarily been more enticing to experimenters, such as bacteriology and experimental pathology. Moreover, a knowledge of these subjects is essential to enable a clinician to apply his therapeutic resources to the mitigation of suffering, the support of strength, and the elimination or destruction of noxious substances. One can safely prophesy that the exact utility and the limitations of drugs and medical procedures will be defined in the present century.

To accomplish this, not only is more knowledge required of the physiologic action of drugs, but also better means of accurately measuring their effects when they are given to patients. We know when pain is relieved we can sometimes measure effects produced upon the heart and blood vessels and temperature. Beyond this we depend for knowledge upon the impressions of physicians, impressions which must be corrected and often reversed by a wide experience. Clinicians possess only a few appliances or methods for the exact study of the sick. It is to be hoped that more will be discovered, and that they will also make it possible to register with accuracy the effect of drugs. When this is accomplished, undoubtedly a smaller number of useful drugs will be employed, but these with greater exactness.

It is true that more drugs are used today than need be, because patients demand them as a fetish; but this will be changed when laymen learn that it is the function of the physician to teach them what to do to give nature the best chance to effect repair, what to do to make themelves comfortable and to preserve life; when they learn that it is a physician's function to teach them how to protect others from the same ailment, to foretell the possibility of recovery or death, and to avert or forestall complications. Medical men should include time and faith in their materia medica as important means of effecting a restoration of health. I do not mean faith in a fetish procured in an apothecary's shop, but faith in the wisdom, honesty and disinterested devotion of physicians which will enable them to accomplish all that can be done for the suffering.

Although the greatest discoveries in the field of internal medicine have been applicable to the prevention of illness in the masses, much has also been done to increase the chances of recovery of individuals who are sick. I need call attention only to a few of the improvements in treatment which have been effected, to remind you of more. Typhoid fever, which has been a scourge in all civilized countries, and constantly present in all larger centers of population, has not only been greatly lessened,—sometimes even suppressed by improved hygiene, but the chances of recovery of the one who is sick with it have been increased several fold by improved methods of treatment. Twenty-five years ago the mortality from typhoid fever in the hospitals of the world was from 20% to 35%; today it is from 5% to 15%. The better results are due to the cold baths which are used, to a more generous supply of fresh air, to proper feeding, and to protection against, or the prompt treatment of, complications.

One great therapeutic discovery has been made at the end of the nineteenth century — the discovery of antitoxins, the natural antidotes to the poisons of infectious agents. For a very long time it had been known that something developed in the human system during the course of many ailments which gave to the sufferer from them for a variable time immunity from a recurrence of the same disease. Until the existence of parasites and of poisons generated by them was proven, an antitoxin was of course unrecognizable. Moreover, the possibility of such a thing in diseases, one attack of which did not cause immunity to others, was not even suspected. But the diphtheria antitoxin, the most efficient of those of which we know anything, is one belonging to this last group of ailments. The chemical composition of antitoxins is yet to be discovered. Since antitoxin has been used the mortality from diphtheria has been reduced about one-half. The most extensive collection[4] of statistics gathered from all civilized countries shows that when antitoxin is used on the first day of the disease, the mortality is 5%, increasing rapidly to 30% when used on the fourth day or later. Before its employment, the average mortality of the disease was from 25% to 35%. To effect a still greater reduction in the death rate from this ailment, it is necessary that it be recognized early, and that

[4] Das Oesterischen Sanitätswesen, 1900, No. 52.

antitoxin be employed more generally as a preventive for those who have been exposed.

That tetanus antitoxin and plague antitoxin are valuable is admitted. Many others, such as pneumonia, typhoid, tubercle, scarlet fever, erysipelas and streptococcus antitoxins are still in the experimental stage. But even though it should be found that few natural antitoxins can be isolated for use as remedies, those already discovered confirm physicians in the hope that specifics will be found some day.

Another therapeutic discovery made at the close of the century which has thrown a flood of light upon some obscure points in physiology and pathology, and has restored to usefulness many who were formerly incapacitated and incurable, is that of internal secretions, and especially the rôle of the secretion of the thyroid gland. Ingredients in the thyroid, suprarenal bodies and ovaries produce as definite effects upon the living body as many extracts from plants or synthetic chemicals. The pituitary body, the thymus, and bone marrow may also have a value as yet undetermined. The rescue of those suffering from myxedema and cretinism by the administration of thyroid is one of the few happy dramatic incidents which fall to the lot of the practitioner of medicine.

That a much larger proportion of recoveries from tuberculosis occur today than formerly is evident from the statistics of this disease, but this lessened mortality is not due to prevention only. Trudeau has estimated that 18% of all persons have tuberculous lesions, because a reaction to tuberculin can be demonstrated in that proportion. This statement is confirmed by Councilman, who states that his autopsy statistics show that at least 17% of all who die have had this disease. But in spite of this prevalence the mortality from the ailment is lessening.

Rabies and tetanus are two diseases which until recently were thought to be incurable. Rabies can be suppressed by killing unowned dogs and by muzzling the rest. Upon this point the following statistics from England are very instructive: In 1887, 217 deaths occurred in Great Britain from rabies; in 1888, 160; in 1889, 312. A muzzling law was then enforced. In 1891 the death rate from the disease fell to 129; in 1892 to 38. The muzzling ordinance was repealed, with the result that in 1894, 248 deaths occurred from mad-dog bites, and 672 in 1895. Again muzzling was made compulsory. The death rate once more diminished to a considerable extent; in 1897 it was 151; in 1898, 17; in 1899, 9; and in 1900, none!

Pasteur's great and wonderful discovery of a method of attenuating the virus of rabies and rendering those who have been bitten by mad dogs immune by rapidly accustoming them to stronger and stronger viruses, has reduced the mortality.

Tetanus, quite common in hospitals formerly, is now prevented by properly cleansing and protecting wounds. It has become so rare a disease that today most students do not see a case of it during their college course.

The nineteenth century will be known in the history of medicine as the century of experimental medicine, for it is in that field that the greatest discoveries of the age have been made. The names of Pasteur, Koch and Lister will forever be linked with it as representing its greatest achievements. But these achievements would not have been possible had not the physicist perfected the microscope, and had not Virchow and his pupils explored the field of cellular pathology to its farthest limits. Around Virchow's name as a banner will historians gather the achievements in medicine during the early and middle portions of the century, and around Pasteur's those of its close.

If our greatest needs conditioned the growth of knowledge, we could prophesy what will be the great field of research of the twentieth century; but history teaches us that our needs can often not be met until some sister science has grown, or new methods of experimenting have been devised. Therefore, the future must remain a blank to us. However, we are more apt to accomplish what is needed if the problems are kept clearly in mind. We greatly need more exact methods of clinical study, more accurate knowledge of the effect of remedial agents and procedures; but more than all else, we need a knowledge of the changes which take place in the living tissue in health as well as in disease.

The anatomist has resolved the cellular structure of the body; the physiologist, the laws which govern the action of its organs and the chemic changes which are wrought upon its surfaces; the bacteriologist has discovered the parasites that infest, and often destroy it; the pathologist has described the anatomical changes which disease produces; the clinician has linked all these facts together, and has discovered ways of seeing with the intellectual eye disturbances of physiologic function, of determining their cause, and of anticipating the anatomic changes which they will produce. But this does not satisfy us; we want a knowledge of the atomic and molecular structure of cells, of the changes which take place in the atoms and molecules in health and in disease, and of the effect of medicines and remedial procedures upon them. This knowledge chemistry must give us. I feel sure that, standing as we do at the beginning of a new century, expecting greater developments in it than in the last one, we are halting before new discoveries in chemistry, waiting for new methods of studying metabolism in microscopic portions of tissue. When this knowledge is vouchsafed, medicine will make another stride as great as was made when, by the perfected microscope, cellular pathology and bacteriology became possible.

Let us look forward with confidence to the Virchow and the Pasteur of the future.

THE next meeting of the American Medical Association will be held in Saratoga, N. Y.

Original Articles.

SOME OBSERVATIONS ON CHRONIC SEMINAL VESICULITIS.

BY ARTHUR L. CHUTE, M.D., BOSTON,

Surgeon to Genito-Urinary Department, Boston Dispensary; Surgeon to Out Patients, Carney Hospital,

AND

RICHARD F. O'NEIL, M.D., BOSTON,

Surgeon to Out Patients, Carney and St. Elizabeth Hospitals; Assistant Surgeon Genito-Urinary Department, Boston Dispensary.

THOUGH disease of the seminal vesicles has been recognized for a number of years, it is only comparatively recently, and largely through the work of Fuller, that men have come to appreciate its frequency and importance.

The writers have recently seen a number of cases of seminal vesiculitis at their clinic at the Boston Dispensary, and feel that their observations may be of interest to others.

The disease undoubtedly occurs without urethral disease, but the writers have seen very few cases of that sort, and the present paper deals only with cases following urethritis.

The number of cases found leads us to believe that this disease is much more frequent than it has generally been supposed to be; the writers found 60 cases of seminal vesiculitis among 540 out patients presenting various sorts of genito-urinary disease. It should be said in explanation, however, that we do not treat syphilis, and that the clinic has a wide reputation among gonorrheal patients. This probably gives us a larger proportion of old and chronic cases of urethritis than some clinics have, and consequently a larger proportion of cases of vesiculitis.

Had we made a systematic search in all patients, we probably should have found a larger number of diseased vesicles, but because of the size of the clinic only those patients were examined in whom urethral disease was unusually stubborn, or who presented symptoms suggestive of possible involvement of the vesicles. A point on which the writers would lay stress is that seminal vesiculitis, secondary to urethritis, is seldom a sharply-defined single disease, but is practically always associated with more or less chronic prostatitis and chronic involvement of the posterior urethra.

The symptoms of seminal vesiculitis may be divided, perhaps rather artificially, into direct and reflex. In any given case the symptoms present may all be of the direct type, all of the reflex type, or a combination of both. As a rule in the long-standing cases the reflex, and on the whole more characteristic symptoms predominate. In the recent cases we more commonly have the direct symptoms, which are often not particularly suggestive of the lesion.

Among the direct symptoms are feelings of vague discomfort in the rectum and perineum, which at times become actual pain; pain and discomfort on defecation; persistence of discharge or shreds, in patients in whom stricture and other gross urethral lesions can be ruled out; particularly suggestive is the persistence of small comma-shaped shreds from the prostatic urethra. Another common symptom is the starting up, without any indiscretion on the part of the patient, of a urethral discharge which had nearly or quite stopped; frequency of micturition is occasionally found, sometimes associated with more or less tenesmus; nocturnal emissions slightly streaked with blood, and the persistence of mucoid discharge from the glands of the urethra. The direct symptoms are for the most part urinary in character, and not particularly distinctive.

The reflex symptoms comprise all the symptoms more commonly ascribed to sexual neurasthenia. There may be suprapubic pain, pain in the back, pain in the head of the penis or at some definite point along the urethra, while the urethra, on endoscopic examination, shows either no abnormality, or none sufficient to give such pain. These pains are often very definite in location, and patients will give the seat of the pain as the same, day after day. Pain along the spermatic cord may occur, and when the disease involves but one vesicle, the pain has been in the corresponding cord.

In the opinion of the writers, the most characteristic symptoms of seminal vesiculitis are the occurrence of irregularities in the function of erection. In the early stages of the disease it is common to have a great increase in sexual desire, which in the later stages gives way to sexual apathy and impotence. In giving their histories, patients with disease of long duration often tell of their former prowess in sexual matters, which they contrast with their present impotent condition. In the earlier stage, patients not only suffer from very frequent nocturnal erections, but the slightest sexual stimulation suffices to bring on an erection which may or may not be accompanied by ejaculation. These erections are usually painless, but when due to the lighting up of an old urethral process, or when a fresh infection of the urethra has been engrafted on a chronic vesiculitis, we may have all the painful elements of chordee combined with the persistence of erection so characteristic of vesiculitis.

Unless one grasps the underlying cause, this sort of chordee is very difficult to control, the usual sedative treatment with bromides, opium, belladonna, hyoscyamus, etc., together with careful emptying of the bowel and hot injection, having little apparent effect. In our experience, these erections have always quieted down very promptly under no other treatment than stripping of the vesicles. We feel that very frequent erections or very persistent chordee is strongly indicative of seminal vesicle disease, as is also the absolute loss of the power of erection in patients who have no lesion of the brain or spinal cord.

While the so-called neurasthenic symptoms, combined with the above-mentioned irregularities of erection are highly suggestive, almost pathognomic of this trouble, the only way in which an

absolute diagnosis can be made is by rectal examination.

For examination the patient should present himself with an empty rectum and a moderately full bladder; he should stand with his feet apart, bending well forward over a chair, and his legs should be straight at the knee. The digital examination can be materially helped by the examiner making suprapubic pressure with his hand, or, still better, with his closed fist; this will crowd the pelvic viscera down so that the vesicles are more accessible. One can considerably increase his reach by putting his foot on a stool and making pressure with his thigh against the elbow of the examining arm.

At first it is a little hard to acquire reasonable accuracy in telling what one feels, and one's ideas of the prostate as it is usually described are rather upset. It is not at all uncommon to find a large prostate in a young man and a small atrophic one in a man approaching old age. In some patients one can feel both the vesicles and ducts when they are diseased; they are enlarged and hard to the touch, and the patient complains of tenderness when they are palpated. In other cases one feels nothing, and the examination will show only unilateral tenderness, or it may be, tenderness on both sides in the region of the vesicles and ducts. In a very few patients with atonic vesicles in which this disease has been of long duration no vesicle can be felt, nor is there tenderness on palpation. In these patients it is impossible to rule out the disease unless, after carefully stripping the vesicles and ducts, one gets none of the detritus so characteristic of vesiculitis. The appearance of this detritus we shall describe later.

The vesicles and ducts of both sides may be involved, but it is more common to have the involvement unilateral. For some reason unknown to the writers the left vesicle has a peculiar predisposition, which is not unlike that of the left testis in epididymitis.

Rarely one finds what feel like concretions in the vesicles. The presence of such a concretion, in one case at least, was not incompatible with relief.

Combined with the above condition of the vesicles and ducts, one finds various irregularities in contour and consistency of the prostate.

It may be very tender, it may be more or less enlarged, sometimes surprisingly so. This enlargement may be symmetrical, but irregular enlargement is most common. It is not uncommon to have the prostate appear to extend up to a point in the median line, which gives it somewhat the conventional heart-shape, with the base below. This is probably really due to exudate over the ducts, which fuses the structures together and makes it impossible to sharply define the true upper border. There may be little circumscribed indurations in the prostate which have not quite the characteristic hardness of carcinoma, but a hardness suggestive of that condition. When vesicles and ducts on both sides are involved, a raised triangular shaped induration may occasionally be felt on the surface of the prostate, the apex being below. When the disease is unilateral, this raised induration may be felt on one side.

A boggy edematous condition of the center of the prostate near the upper boundary is not uncommon. After massage or steady pressure upon such a spot, one finds that a little depression remains in which the pulp of the finger fits. The large edematous and tender prostates usually go with the more recent forms of disease; the hard and shrunken with those of long duration, although this does not invariably hold true.

Almost as characteristic of vesiculitis as the condition felt per rectum, is the material gotten after massage. This material may either drip from the meatus during the stripping process, or be voided in the urine.

The material, when it oozes from the meatus during massage, is milky, and contains masses of various sizes. If we find, on immediate examination of this detritus, that all the spermatozoa are non-motile, this is almost, if not quite, pathognomonic of vesiculitis; on the other hand, the finding of non-motile spermatozoa in the detritus washed out by urine is not decisive, as the spermatozoa very soon lose their motility when in urine.

The urine voided after massage is usually more or less turbid, with a slightly opalescent tint, and in it there are often little caseous-looking masses which are heavy and fall to the bottom of the glass. These are made up of epithelial and pus cells. Another very striking thing is the presence of large, partly rolled plates of mucus. These look like shavings of paraffine, and float about. They soon settle, however, and then, particularly if the urine is acid, very quickly disappear. If these paraffine-like flakes are removed from the urine at once, and their method of vanishing followed, it will be found that they soak up fluid and become transparent, gelatinous masses, which under the microscope show masses of mucus, in the meshes of which are a few leucocytes, some epithelial cells, and at times many spermatozoa, as well as various bacteria.

The treatment which has given the writers the best results in these cases of vesiculitis is massage of the vesicles and ducts and of the prostate as well. One cannot massage the vesicles without incidentally massaging the prostate to a certain extent; but the writers feel that because of the involvement of the prostate, it should receive definite attention.

For massage the patient's rectum should be empty and the bladder moderately full. He should pass enough urine to wash out the urethra, but should hold some in the bladder. The patient then assumes the position spoken of in examination for the disease. The surgeon introduces his right forefinger, making strong pressure against the perineum. The bracing of his arm, previously described, and strong supra-pubic pressure, are of great assistance. The ducts and vesicles are then gently stroked in a downward direction, using only the terminal phalanx of the finger. The

prostate is then treated in much the same manner, though the pressure used on the prostate may usually be greater than that used on the vesicles, without causing discomfort.

At the beginning of treatment, or when the vesicles are very tender, the time of massage is very short. At first the patients are massaged at intervals of from five days to a week. Later the intervals are longer and the massage more thoroughly done.

In some patients the detritus from the vesicles will be seen to drip from the meatus during massage; in others none is seen until the patient passes the urine retained for the purpose of washing out the urethra. The amount of material thus obtained varies greatly. It occasionally happens that at the first attempt nothing is gotten, while at a subsequent treatment there may be a great deal of the detritus.

During massage a sort of semi-erection is common, also an almost uncontrollable desire to urinate. If the patient, in spite of injunctions, has emptied his bladder, and one finds that he cannot pass urine after massage, it is wiser, in our opinion, to fill his bladder with mild corrosive, permanganate or nitrate of silver solution, and then allow him to pass it. In the majority of cases it is perfectly safe to let him wait until his next micturition; but in a few instances a mild cystitis has followed massage when the refuse has not been washed out at once.

In the greater number of cases the chronic prostatitis and the chronic posterior urethritis need no attention other than the massage.

In some patients, however, when the disease has been of long duration, and presumably accompanied with more or less round cell infiltration in the submucous tissue of the deep urethra, dilating with Oberlaender's or Kollmann's dilator seems to have a beneficial effect. Of these two instruments the Kollmann, while much the more expensive, is in our opinion vastly superior. It apparently opens the mouths of the glands of the prostatic urethra, and allows any solution to enter them freely. It is also probable that the pressure exerted on the infiltrated submucous tissue aids in absorption. With this dilation we use rather strong solutions (5%) of nitrate of silver applied with a deep urethral syringe. In some cases they seem to aid materially; in others they have been badly borne and had to be given up. Hot rectal irrigations through a double current tube have given a good deal of benefit in some cases; in quite a proportion they seem to have no effect; in a few they seemed to aggravate matters, and had to be omitted. We have used the various balsamics in conjunction with massage in a number of patients, though we are yet to be convinced that they are of any real benefit. Tonics and hygiene have in this condition a distinct though entirely secondary place.

The treatment which is of greatest benefit and apparently curative, so far at least as subjective symptoms go, is the mechanical emptying of the diseased vesicles and ducts.

The writers wish to utter a word of warning against the treatment of vesiculitis by regulated sexual intercourse. This treatment they have lately heard advised, and it would probably appeal to many patients.

In the impotent cases with atonic vesicles it is of course out of the question. In the cases in which it seems plausible, namely in those suffering from frequent erections and emissions, it has proven itself useless. Had it been curative we should not find the atonic cases, as most patients would have cured themselves during the early stages when the sexual appetite is so stimulated that they often commit great excesses. The failure of this treatment is due to the fact that the diseased vesicles do not empty themselves during intercourse.

The writers have examined two patients the day after they had, against advice, indulged in coitus. These men had been under treatment regularly, and the amount of detritus did not vary to any extent from the usual amount. To allow sexual intercourse occasionally when the treatment is pretty well advanced seems to us probably not harmful, but to advise it as a therapeutic measure is, we think, a great mistake.

As to the results obtained with these cases: a few who have had no subjective symptoms for some time have been discharged. It depends on one's definition of the word "cure" as to whether they could be styled cured. If one demands only that the subjective symptoms shall have disappeared, they are cured. If one demands that the prostate and vesicles shall have become normal in appearance and that there shall be no detritus from the vesicles, they are not cured.

A great many have disappeared without being discharged, having become very much better, so far as subjective symptoms go, although without a corresponding improvement objectively.

One patient who had not had an erection for some two years has become so that erection takes place with about normal frequency. Men who have had vague pains for a long time have gotten rid of pain. Several suffering from abnormal frequency of erection have improved. Many men having urethral discharges of long duration are well. Marked improvement has been noted in the mental attitude of those patients in whom the neurasthenic element was very noticeable.

Coincident with the improvement in symptoms, there is often a marked improvement objectively: the ducts and vesicles become less tender and less easily palpable; the detritus grows less; the big and soggy prostates, as well as the hard and atrophic ones, tend to become more normal in contour and consistency, the big prostates decreasing in size and the small prostates increasing.

The more recent cases do best, as would be expected, and the younger patients, with a few exceptions, improve much faster than those above forty.

We think we may expect that all cases of vesiculitis can be greatly benefited by careful treatment.

In the majority the subjective symptoms can be made to disappear for at least a considerable time. For the older patients, especially for those having disease of long duration, we feel that massage will probably have to be used now and then, that they may be kept comfortable. They are much better for a few days immediately after massage than they are a little time later. Even if these patients are benefited only temporarily, the treatment is well worth while.

In the opinion of the writers it is probable that a certain number of the cases of impotence and many of sterility are due to vesiculitis; this gives its treatment a wider importance than the mere remedying of the discomfort the patients suffer.

We would strongly advise the examination by rectum of all patients with urethral disease, recent or of long duration, in which the disease is not progressing favorably, particularly of those showing the so-called neurasthenic symptoms.

As the writers have attempted merely to give their own clinical experience with seminal vesiculitis, they purposely have omitted the subjects of etiology and pathology, and have not attempted to compare their observations with the experience of others.

IODOPHILIA.[1]

BY THEODORE DUNHAM, M.D., NEW YORK.

I HAVE ventured to coin this word to designate a reaction which occurs in the blood under certain pathological conditions. I bring this subject before you because this reaction has been a definite help to me in diagnosis, and I feel that it deserves a more extended use than it has yet received. The cases in which it gives aid are those of doubtful suppuration and doubtful pneumonia. We are not infrequently confronted with cases of appendicitis where an additional aid to the early recognition of pus would be of the greatest value; and there are other cases of deep-seated trouble with doubtful physical signs where an additional means of throwing light on the presence or absence of pus would be a great help. Pneumonia is often difficult of recognition during the first few days after the onset. An additional aid in diagnosing it during this stage would be of real value.

Let me say a word about the technique of the reaction and then speak of its clinical bearings.

The technique is very simple. It consists in the staining and examination of a spontaneously dried blood smear. The smear need not be stained at once, but will be good for use several weeks at least after making. It is thus possible to make the smear at the bedside and send it to the laboratory for staining and examination.

Only one solution is required, and this is made up as follows: Three parts of potassium iodide are dissolved in one hundred parts of water. In this is dissolved one part of iodine. The resulting solution is thickened to a syrupy consistency by the addition of lumps of gum arabic and occasional shaking until they are dissolved. The blood smear is mounted in a drop of this syrup and a bit of filter paper placed at an edge of the cover glass to absorb the excess of fluid. The specimen is then ready for examination by an oil immersion lens. When blood is treated in this way the lymphocytes and the eosinophiles are not affected by the stain. In normal blood the polymorphonuclear neutrophiles are either unaffected or their protoplasm is tinged a faint pinkish or brownish color. Under some pathological conditions, however, the protoplasm of a certain proportion of the polymorphonuclear neutrophiles takes on a reddish-brown coloration. The mode of coloration differs in different leucocytes; in some it is a diffuse stain; in some a granular network; while in others the color is confined to large or small refractive granules, varying in tint from a light pink to a dark red. Where one or more such leucocytes can be found in a search of a few minutes we have the condition to which, for the sake of brevity, I have ventured to give the name "iodophilia."

It is apparently always present in progressive suppurations and in progressive pneumonias. It may also occur in a few other diseases, but they are fortunately easy of recognition in other ways and not to be confounded with abscess or pneumonia. I will refer to them later. First, let us consider the iodophilia of acute suppuration. The intensity of the reaction is said by other observers to be closely related to the intensity of the process, and I have found this to be true in the cases I have examined. Small abscesses will, however, if the process be active, give a distinct reaction. In cases of so-called tubercular abscess the reaction is absent. Abscesses caused by the germs of acute suppuration, but which are well walled off and have assumed an indolent course, rarely give the reaction. If, however, the process lights up again, the iodine reaction is said to return. Goldberger and Weiss, from an examination of a considerable number of other diseases as well as of abscess, reach the conclusion that a distinct intracellular iodine reaction, even if made out in only a few leucocytes, warrants the conclusion that there is present a progressive suppurative process. In reaching this conclusion, of course the few other lesions which give rise to iodophilia must be excluded.

I shall not weary you with details of all the suppurative cases in which I have tested for iodophilia. Suffice it to say that I have found it in every case where the abscess was of any size and the process of any virulence. I will speak in detail of only 3 cases in which the finding of iodophilia was an aid in reaching a correct diagnosis.

D. K., age seven and one-half months, was admitted to the Babies' Wards of the Post-Graduate Hospital with an adenitis of the neck. No previous history was obtained. The process was not acute, and at first I thought the gland tubercular. The leucocytes were 19,700. Iodophilia was very

[1] Read before the Warren Club, of Boston, March 28, 1901.

striking in some leucocytes. At operation I found the gland had broken posteriorly, and my finger passed in the pus cavity between the spine and the upper part of the trachea. The pus showed streptococci.

A. M., a girl of thirteen years, was admitted to the service of Dr. Joseph D. Bryant at Bellevue Hospital, suffering from a not very acute appendicitis. She had had right iliac pain for five days. The leucocytes were only 12,200. The iodine test showed diffuse browning of many leucocytes, and a few contained brilliant iodophile granules. Here the leucocytosis was low, but the iodine reaction pointed to pus. The case was operated upon three hours later, and a considerable amount of pus was found.

M. K., a boy five years old, was admitted to the Babies' Wards with a history of excellent health until three months prior to admission. His illness began with general misery, soon followed by a marked jaundice. The jaundice lasted several weeks. When it disappeared he was still sick and had fever. For a time he was treated as a typhoid. Then his disease was diagnosed as appendicitis. Finally a tumefaction was discovered in the region of the gall bladder. When I first saw him he was in a rather low condition, running a very erratic temperature which fluctuated between 99° and 105°. In the neighborhood of the gall bladder was a tumor, very hard, rather tender, and just visible to the eye. I found the leucocytes 21,800. A blood smear showed a number of iodophile leucocytes. On opening the belly I found what the iodophilia would indicate: an abscess. It was the size of a pigeon's egg, in the substance of the liver near its margin, and about three-quarters of an inch from the surface. The pus gave a pure culture of staphylococcus pyogenes aureus.

In the 3 foregoing cases the presence of iodophilia helped either to make or clinch the diagnosis.

Let me now speak of the relation of iodophilia to pneumonia. Other observers say that the iodine reaction occurs constantly in pneumonia. I have found this to be true in the cases which I have examined. The reaction would not be of great value in pneumonia if it were present only when consolidation was so far advanced as to give a typical picture of the disease, for then the usual diagnostic signs are sufficient. But in 2 cases where I examined the blood at an early stage, before physical or other signs were specially suggestive of pneumonia, I found a well-marked iodophilia. This early appearance of iodophilia in pneumonia I have not seen referred to by others, and know of it only from the two instances where I looked for it. If it proves to be uniformly present soon after the onset, iodophilia will be one of the earliest diagnostic signs of pneumonia.

I will cite 3 cases in which I had failed to diagnose pneumonia prior to finding iodophilia, but where a pneumonia was subsequently proved to exist.

S. Di M., age forty-seven days, was admitted to my service at the Babies' Wards in a moribund condition. The left femur was the site of an ununited fracture which had probably occurred at birth. The child had been artificially fed and poorly cared for. Respiration was feeble. I could make out nothing abnormal in the lungs. The blood showed iodophilia. At the autopsy there was found a bronchopneumonia of the left lung.

E. K. D., age forty years, was taken suddenly with chilliness, intense facial pain, sore throat, and a temperature of 102.5°, apparently an attack of grippe. In the evening of the second day his temperature was 104.3°, and Dr. Janeway, who saw him in consultation with me, found a suspicion of râles in the right lower lobe. In the morning of the third day I found as light pleuritic friction at one spot over the right lower lobe. At noon I examined the blood for the first time. There was a leucocytosis of 27,600 and iodophilia was present. Later in the afternoon Dr. Janeway found the signs of a coming pneumonia of the right lower lobe. That night there was rusty expectoration, and the sputum contained pneumococci. Solidification progressed.

C. T., a boy age three years, was in my service at the Babies' Wards under treatment for stricture of the œsophagus. His general vitality was low, but he was up and about the ward. One evening his temperature shot up to 105° without other noteworthy symptoms. The next morning it was 104°, and in the afternoon again 105°, with the pulse 180 and the respiration 38. Examination of the chest was negative. I found a leucocytosis of 55,800 and a well-marked iodophilia. On the strength of these findings I suspected a beginning pneumonia. A day and a half after I had found the iodophilia, signs of partial consolidation showed in one upper lobe. He ran a regular course of lobar pneumonia, the fever continuing high for five days.

In these 3 cases the finding of iodophilia was a help in diagnosing the presence of pneumonia. Two of the cases showed it to be an early sign.

As I have already said, certain diseases must be eliminated from the diagnosis before one concludes that iodophilia implies the presence of pus or pneumonia. Hofbauer at Neusser's clinic in Vienna found that iodophilia occurred in certain grave blood diseases. In 18 cases of chlorosis he failed to find it. In 18 cases of secondary anemia he found it in 2, but one of these was complicated by pyothorax and the other by gonorrheal adnexa, and its presence was probably due to these complications. But in really grave anemias, as that associated with cancer of the stomach, severe chronic intoxications, etc., where the blood picture approached that of pernicious anemia, he regularly found a greater or less number of iodophile leucocytes in the 7 such cases he examined. In advanced pernicious anemia and in leukemia he also found it. I found it very marked in the one case of leukemia which I have examined in this way.

As iodophilia is a natural accompaniment of these diseases, in them its presence throws no light on the existence of pus or pneumonia. During an examination with the iodine test these grave blood diseases would surely be recognized. With their elimination, the finding of iodophilia points to acute suppuration or to pneumonia.

Clinical Department.

CONTRIBUTIONS FROM THE LONG ISLAND HOSPITAL, BOSTON HARBOR.

CYSTIC TUMOR OF MEDIAN NERVE; OPERATION: RESTORATION OF FUNCTION.

BY A. S. HARTWELL, M.D., BOSTON,

Assistant Superintendent and Physician, Long Island Hospital.

A WOMAN, eighteen years old, was admitted to the Long Island Hospital November 15, 1900, said to be suffering from syphilis. The history dated back four months, and was in substance as follows: An eruption on the chest causing much itching, and a swelling at the right elbow, just above the joint, which was increasing in size and tender.

Examination showed a freely movable tumor at the inner edge of the biceps muscle on the right forearm, about 5 cm. above the joint.

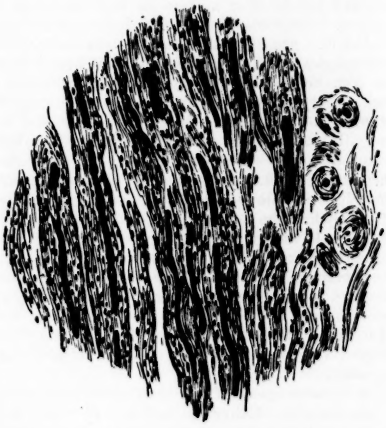
It was about the size of a chestnut. Moving it about caused tingling down the forearm and into the hand through the distribution of the median nerve, in which there was also loss of sensation to touch and pain. There was likewise considerable paralysis of motion. A diagnosis of tenia versicolor of the chest was made, and the swelling was thought to be a tumor of the median nerve. Syphilis was ruled out.

Operation showed the following condition: The median nerve was enlarged to a fusiform-shaped tumor 4 cm. long by 1.75 cm. wide. The fibres were separated, and between them and in the center of the tumor was a clear, colorless fluid somewhat thicker than water. Tearing the fibres apart, the fluid easily escaped, leaving the nerve slightly enlarged and edematous, but otherwise apparently normal. A small piece of the nerve was removed for examination and the wound closed.

It healed readily, and there was considerable pain in the arm for several days following the operation. Ten weeks after operation there was no return of the tumor, no pain or sensory disturbance, and, excepting slight weakness in the arm, it appeared to be normal. The skin eruption disappeared upon application of local treatment.

Pathological examination.— Examination of a portion of the nerve excised showed macroscopically no changes. Sections stained by the Weigert hematoxylin method show a considerable separation of the individual fibres, a very marked thickening of the sheaths of Schwann, and an almost complete disappearance of myeline (see figure). The axones cannot be clearly distinguished in a section stained by Van Gieson's picric-acid-fuchsin solution. A nuclear stain (hematoxylin) shows a very considerable proliferation of cells of the connective tissue surrounding nerve fibres, but nowhere is a distinct new growth to be made out. The nerve, in general, presents the appearance of edema, with proliferation of connective tissue elements and degeneration of nerve fibres. It may be surmised that the pressure exerted on the nerve by the presence of the cystic tumor secondarily led to the intrinsic alterations of the individual nerve bundles.

The case is again interesting from the fact that the patient was sent to a physician previous to her admittance to the hospital, who pronounced the affection syphilis, because, as the patient stated, of the rash on the chest and an enlarged gland at her elbow. The relatives with whom the patient lived were told of her supposed condition, which resulted in her being sent away from home



in disgrace. The injustice of so openly declaring a case to be one of syphilis, without the most convincing evidence, is well illustrated here.

The patient was again seen May 27, 1901. The improvement following the operation has been continuous; she has gained 12 pounds in weight, and is able to use the affected arm for all purposes, noticing only a somewhat increased awkwardness in making finger movements. Gross strength is essentially unimpaired, and all movements of the hand and arm are possible. There is still considerable tenderness over the scar of the operation, and occasional radiating pain in the forearm, especially on exertion. Sensation is objectively impaired only in the terminal phalanges of the middle finger of the right hand, in which there is almost complete loss of the temperature, pain and tactile senses. Examination with galvanism shows a good reaction from the

median nerve above the seat of operation, a slight quantitative diminution of excitability in the flexor muscles of the forearm, and a complete reaction of degeneration — slow response, AnC greater than CaC. — in the small muscles of the thumb. The patient regards herself as essentially well, and there is certainly no present evidence of a return of the cystic tumor.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY F. B. LUND, M.D., BOSTON.

THE IMMEDIATE AND REMOTE RESULTS IN ONE HUNDRED CONSERVATIVE OPERATIONS ON THE OVARIES AND TUBES.

Burrage[1] reports the results in 100 cases of conservative operations upon the ovaries and tubes which have been under observation a year or more after the operation.

Classing as conservative operations all those in which an operation upon the appendages being performed (not including suspension of the ovaries or hysterectomy), one ovary, a portion of an ovary, or one tube or a portion of one tube, was left behind, he had performed 156 operations with 3 deaths.

During the early operations marked enlargement of resected ovaries had been noted in the weeks immediately following operation, the enlargement disappearing in the course of time, but being attended by pain. These phenomena had latterly been less frequently noted, and the writer thought the enlargement to have been due to hemorrhage from the free puncturing of cysts without careful hemostasis, and due to hemorrhage as well as trauma. Pelvic inflammatory exudate about ovary and tube had been noted in a few cases following resection of a closed tube, these being old gonorrheal cases which had suffered repeated attacks of pelvic inflammation.

In other respects convalescence from operation had been as uneventful as in other similar operations where ovaries and tubes had not been resected. As a general rule, conservative operations require for their performance a somewhat longer time than radical operations, a fact which should be remembered in operating on enfeebled patients.

The greatest interest centres in the late results of the preservation of ovarian and tubal tissue. In the instances where the writer has left an ovary or part of an ovary in doing hysterectomy, the symptoms of the artificially induced menopause have seemed to be lessened. There is a possibility of pregnancy occurring in the tube or the abdominal cavity where the uterus has been removed and the ovary and tube left, and such an instance has been reported.

In summarizing his 100 cases, the writer finds a symptomatic cure in 73, and no relief in 27. From the fact that a large number of the patients were pronounced neurasthenics, and from the difficulty of estimating the relative share of the sexual organs and the nervous system in the symptom complex, the writer thinks that too much weight ought not to be attached to these figures.

Anatomical cure (ovaries and tubes normal to feel, and well placed) was noted in 44 out of 69 cases which came under observation, or 64%. Some enlargement or prolapse of ovaries and tubes was found in the remaining 25 cases. Pregnancy following operation occurred in 19 cases. In no instance, however, did pregnancy result after resection of a closed tube, both tubes being closed at the time of operation.

After correcting his tables by deducting from the list of married women those who afterwards had oöphorectomy or hysterectomy performed, who became widows or took measures to prevent conception, and adding those who became married after operation, Burrage found that $32\frac{7}{10}\%$ became pregnant. All of the cases of subsequent pregnancy except 3 had been pregnant before the operation, so that $34\frac{1}{2}\%$ of those who had previously borne children became pregnant after operation, while only $6\frac{1}{3}\%$ of those previously sterile subsequently became pregnant.

Several of the unsuccessful cases were in women over thirty-five years old, with extensive, long-standing tubal and ovarian disease; it would seem less desirable to subject such cases to conservative operations than the younger women with the same trouble, for at this time of life the patient is suffering not so much from the ovarian and tubal affection as from the long-continued effects of it. There is little chance that the uterine organs, diseased for many years, will be able to regain an approximately normal condition in the few remaining years of functional activity, both because of the limited time and because the reparative processes of the system are less vigorous than at an earlier age. Therefore these patients either need no operation at all, or one which will entirely eliminate the ovarian function, thus doing away with the monthly pain and discomfort, which are an additional burden to an already jaded nervous system.

As bearing on the question of resected ovaries becoming diseased at some future time, the writer found that out of 85 cases, in only 1 case, a syphilitic, was another operation necessary for subsequent enlargement of an ovary resected for cystic disease.

In 3 instances in which one ovary was removed and cysts punctured in the remaining ovary, another operation was required for disease of the ovary left behind. In 7 other cases a remaining ovary, cystic at the time of operation, was later noted as being large, though causing no ovarian symptoms.

In 5 cases of the extensive purulent inflammatory type, all of them gonorrheal and 3 syphilitic, one ovary and tube being removed in each case, the remaining ovary became diseased following operation, and another operation was indicated,

[1] Medical News, April 13, 1901.

although only one of the patients had actually submitted to it.

In 2 cases a diseased ovary was left at the bottom of the pelvis, once after the removal of the sac of an ectopic pregnancy and once after the removal of a pus tube. Both of these women had suffered pain since the operation, but neither had been willing to be operated upon again.

As far as the writer had been able to determine, the amount of ovarian tissue present had no definite relation to the amount of menstrual flow or the intensity of sexual desire and gratification.

The most unfavorable cases for conservative operations are the pronounced neurasthenics who are approaching the menopause, patients with long-standing gonorrheal infection, and those having both ovaries thoroughly riddled with cysts.

REPEATED EXTRA-UTERINE PREGNANCY.

Varnier and Sens[2] present the following conclusions derived from the study of 65 reported cases of repeated extra-uterine pregnancy, in 36 of which the diagnosis was established absolutely by the finding at the operation of either the fetus, chorionic villi or decidua.

(1) Repetition of an extra-uterine pregnancy is much more frequent than is at present recognized. It ought to be made a most important factor in the prognosis as to continued health which is made in these cases, for there is a distinct tendency to repetition in this disease.

(2) This recurrence almost always takes place in the opposite tube, it having been noted in the same tube only once in the 65 cases. In 43 cases of recurrence in which mention is made of the tube which was the seat of the first attack, we find that this first pregnancy involved the left tube 16 times and the right tube 27 times.

(3) The time which elapsed between the first and second pregnancy is noted in 56 cases; the time noted, however, being generally that which elapsed between the first and second operations for the condition, and varying between six weeks and twelve years.

(4) In only 6 out of the 65 cases did a normal pregnancy intervene between the ectopic pregnancy and its recurrence. Only 3 times did this intercurrent normal pregnancy go on to full term; in the 3 others a miscarriage occurred.

(5) There seems to have been a tendency on the part of the recurrence to follow the same type with reference to location, method of evolution, etc., as the first attack. In a number of cases both ectopic pregnancies went on to an advanced period, in close resemblance to normal pregnancies, without pain, hemorrhage or peritonitis, until false labor, with retention or expulsion of the dead fetus, established the diagnosis.

(6) In regard to the few reported cases in which ectopic pregnancy is alleged to have occurred three times in the same patient, a careful analysis fails to show that in these cases the diagnosis has been established beyond question, although it is not impossible for such a case to occur, as it has been demonstrated that ectopic pregnancy may take place twice in the same tube, even when the tube has been ruptured the first time.

(7) Leaving out of account, however, the very exceptional cases in which the same tube is twice affected, the fact remains established that when ectopic gestation has occurred in one tube, there is a distinct tendency to its recurrence on the opposite side; and the question must be asked: What is the analogous condition of the tubes which predisposes them to become the seat of ectopic pregnancies? One is led naturally to believe that the tubes successively affected present some identical predisposition, either congenital or acquired, which might be discovered by a careful examination of the unaffected tube at the laparotomy performed for the relief of the first attack. Unfortunately, however, the shortness and inaccuracy of the reported observations renders the establishment of any generalization upon this point difficult. In an effort to analyze the reported cases with regard to this question, the writers are able to get some facts of value, and their conclusions follow:

(1) In 51 cases in which the previous history is given, 40 concerned multiparæ and 11 nulliparæ. We have, then, 11 cases in which the genital organs have been abnormal in function from the first. This abnormality was repeated by a recurrence of the same sort in 2 out of the 11; in one of them, that of Duff, an abortion at nine weeks intervening between the 2 ectopic pregnancies. In 2 of these women, after five and seven years of sterile married life respectively, ectopic pregnancy occurred in both tubes successively. It is in cases such as this that Freund's hypothesis of "bilateral arrest of development of the tubes preventing the descent of the fecundated ovum, and arresting it in one of the infantile sinuosities of the oviduct," appears reasonable.

But of the 7 cases of this group in which two laparotomies were performed, in only 1, that of Boisleux, was the condition of the non-gravid adnexa noted during the first. In Boisleux's report he states that "the tube and ovary on the left side appeared normal."

Brosin, who did not examine the condition of the opposite adnexa at the first laparotomy, but did examine the specimens removed, states his opinion that in his case it was improbable that the second ectopic pregnancy was in any way due to the conditions resulting from the first,— at least there were no adhesions found, either to the parietal incision, to the pelvic wall, or to the viscera. He found abnormal sinuosities and complicated windings of the lumen of the first tube below the dilated portion, and is inclined to the belief in a congenital cause for both pregnancies. There is so little evidence on this point that the importance of careful observation of the non-gravid tube at a laparotomy for this condition in a multipara is evident, and such observation ought to be practiced in every case.

[2] Ann. de Gynak. et d'Obstet., March, 1901.

(2) In case of recurrent ectopic gestation in women who have previously gone through normal pregnancies, we are led to think of changes resulting from puerperal peri- or endo-salpingitis arresting the descent of the ovum. In these cases note of the condition of the opposite tube was made only 8 times, and in 2 of these the statement is made merely that the tube was "diseased." Falk found at his second laparotomy he had to deal with bands and sheets of old adhesions resulting from the first operation, and is inclined to attribute to these a causative relation to the second attack.

Lindblom operated in 1896 upon a woman who had had five normal pregnancies, followed in 1895 by a retroflexion, endometritis, and right oöphoritis for which vagino-fixation was performed. At the laparotomy the tube and ovary were found surrounded by firm adhesions, which confirms the hypothesis that pathological conditions of the tube are a frequent cause of abnormal implantation of the ovum.

In the six other multigravidæ, where the opposite tubes were examined, they were reported healthy. It seems not improbable that the adhesions due to the organization of the exudate about the tube removed at the first operation may be the cause of the second pregnancy. To those who object that ectopic gestation does not follow removal of a single tube and ovary for other causes, the reply is made that such operations are done either for a simple ovarian cyst, in which practically no peritubal adhesions on the opposite side would result, or a salpingitis, in which lesions of the mucosa on the side preserved would prevent impregnation.

On the other hand, the statement that the opposite tubes were found "healthy" at the first operation does not prove much, for the reason that alterations of the mucous membrane, or an occlusion, might escape such observation. As to endosalpingitis, many authors consider it incompatible with impregnation, and Bland Sutton makes the paradoxical statement that a healthy tube is more likely to become impregnated than one which has been inflamed. Others (Boldt, Martin, Dührssen) state that a catarrhal endosalpingitis, if of slight character, favors the occurrence of ectopic gestation.

The writers, in conclusion, call attention to the real poverty which prevails amid the apparently rich store of observations which have been accumulated of recent years, and urging the attention of future observers to the undecided points.

(To be continued.)

BETWEEN 1892 and 1894, inclusive, according to the *Philadelphia Medical Journal*, there were 1,475 deaths from cholera, while the number of deaths from tuberculosis during the same period reached 10,650. The annual mortality from tuberculosis all over Russia is between 360,000 and 450,000, while the number of persons affected with the disease is estimated at 2,000,000 to 2,500,000.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

ABSTRACT REPORT OF THE SIXTEENTH ANNUAL MEETING, HELD AT WASHINGTON, D. C., APRIL 30, MAY 1 AND 2, 1901.

(Concluded from No. 23, p. 564.)

SECOND DAY.

STUDY OF BUBONIC PLAGUE.

DR. FLEXNER considered the pathology of this affection. He said that the glandular enlargements could not be mistaken for those occurring in any other disease. The bubonic condition is characterized by a peculiar hemorrhagic edema, which is not limited to the gland, but involves its surrounding tissues for some distance, and shows numerous foci of necrosis. The enlargement is due to multiplication of the cells normally present in the gland, in addition to the edema, and to the enormous growth of bacteria, which is greater than in any other disease, with the possible exception of the skin lesions of leprosy. The necrosis is due to the presence of toxins and bacilli in the blood vessels.

The pneumonia is usually lobular in character, and the exudate contains enormous numbers of the bacilli, making up a very considerable part of the material which fills the alveoli, and produces the consolidation. The changes in the spleen are those of acute splenic fever, and the organ is enlarged occasionally to five times its normal size.

He said that he expected to hear soon that plague has disappeared from San Francisco, and that the statement, when received, will be reliable, in that it will be based upon bacteriologic demonstration; for the city and State authorities, acting with the United States Government, have carried out the recommendations of the commission for the erection of a public mortuary, and for the establishment of a retention camp, in which suspected cases will be kept under observation.

DR. STERNBERG, in the discussion, attributed the very prompt suppression of the San Francisco epidemic to the fact that there were on the spot trained bacteriologists, with laboratories at command, who promptly recognized the disease. He referred to the conditions existing twenty-five or thirty years ago, when a most serious epidemic would have most probably followed the entrance of a case into this country.

DR. PARK related the history of two cases of plague which recently entered the port of New York on a coffee-ship. They were of a mild type; both got well, and no other cases followed.

DR. VAUGHAN reported a case occurring at Ann Arbor, where a student, working with Dr. Novy's cultures in the laboratory, infected himself. The student was promptly isolated, together with those of his associates who had been near him; his room was disinfected, and the laboratory closed. The patient's condition became very serious, and required the most vigorous use of the antiplague serum. Recovery followed.

DR. DOCK exhibited the temperature chart of this case, and explained its clinical history. It was of the pneumonic type, and the more acute stage was followed by a prolonged heart weakness.

DR. BARKER congratulated the Ann Arbor physicians on their prompt recognition of this case, and upon their successful efforts to prevent an epidemic, as well as their saving the patient. He added, that probably all cases of plague are contagious, and that attendance upon such cases, and the making of autopsies, are both attended by a certain amount of danger. Patients with the pneumonic type of plague should have their mouths covered by a fine veil, and anyone going near them should cover his own mouth and nose with a fine sponge.

DRS. WALTER REED and JAMES CARROLL, U. S. Army, read papers on

EXPERIMENTAL YELLOW FEVER.

DR. REED gave a detailed account of his recent work in yellow fever, adding the histories of a number of cases not heretofore recorded. As in the first instances, however, they show very definitely that the poison of yellow fever is carried in the circulation, and can be transmitted from one person to another by mosquito inoculations, or by direct transmission of the blood hypodermically.

DR. STERNBERG, in the discussion, referred to the importance of these demonstrations, which have made clear a number of facts that have heretofore seemed contradictory. For instance, ships arriving from Havana, without any cases of yellow fever aboard, would be unloaded by stevedores, a number of whom would soon develop the fever. It is now clear how they succeeded in disinfecting such ships by sulphur dioxide. The burning sulphur destroyed mosquitoes hanging about on the ship's timbers; whereas, it could not have produced disinfection if it were necessary to penetrate the cargo. This work also explains how yellow fever was contracted from passing ships, with which no communication had been held.

DR. STERNBERG referred to his own work in the effort to determine if there was anything in the blood of yellow fever patients that would give the disease to others, and said, that now that the intermediate host had been discovered, he hoped it would not be long before the parasite itself was isolated.

DR. WELCH congratulated Dr. Reed on the success of his experiments, and called attention to the American soldiers who had so nobly assisted the work by submitting themselves as experimental subjects, saying that they deserved to be known in the history of the army and in medical circles as true heroes.

DR. JAMES EWING, of New York, reported

A CASE OF MALARIAL NEPHRITIS, WITH MASSING OF THE PARASITES IN THE KIDNEY.

Microscopical examination of the kidneys of fatal cases of malaria yielded evidence of three main types of acute renal lesions occurring in this disease: (1) Acute degeneration of toxic origin, often reaching a degree in which exudation of blood serum into the tubules is added, is responsible for the vast majority of the cases of albuminuria in malaria; (2) an extreme form of acute degeneration with focal necroses, which is seen in cases of hemoglobinuric malarial fever; (3) massing of parasites in the renal capillaries with extreme degeneration of parenchymatous cells, hemorrhages and exudation into the tubules. This is seen only in severe estivo-autumnal infections.

DR. WALTER B. JAMES, of New York, read a paper on

SEPTIC INFECTION THROUGH THE STOMACH AND DUODENUM.

It is generally assumed that septic poisoning rarely takes place through lesions of the stomach and duodenum. Influences that operate against such are the inhibiting effect of the gastric contents upon bacterial growth, and the effective protective mechanism supposed to reside in the liver and to operate upon such elements as find their way into the portal stream. The author was led to inquire into the subject through the occurrence in his practice of several cases in which the clinical picture, and in some instances the results of the post mortem, pointed to the existence of septicemia, where it seemed probable that the portal of entry for the infecting organisms had been lesions of the stomach or duodenum. Dr. James reviewed the recent work to show that the evidence proves that the stomach and duodenum practically at all times contains large numbers of bacteria that are taken with the food, and are in an active state capable of exerting their peculiar influences and producing a septic condition should a solution of continuity take place in the mucous membrane. Illustrative cases were given to show that severe and even fatal septicemia may have its starting point in an ulcer or similar erosion in the mucous membrane of the stomach.

DR. KINNICUTT said that he had long believed and taught that the fever so frequently noted in ulcer and cancer of the stomach is the result of infection from the gastric lesion. Another observation which tended to confirm this opinion was the presence of some of the less grave conditions of infection, such as suppuration of the parotid and other glands occurring in ulcer cases.

DRS. J. H. MUSSER and N. B. GWYN, of Philadelphia, reported

TWO CASES OF STREPTOTHRICAL INFECTION: (1) BRONCHOPNEUMONIA; (2) ABSCESS OF THE BRAIN.

The first case was one of bronchitis of several weeks' duration, due to a mixed infection and terminating in bronchopneumonia. The sputum showed micro-organisms having the characteristics of streptothrix, and also of the branching forms of tubercle bacilli. Inoculations and cultures did not show them to be tubercle bacilli.

The second case was that of a young man in whom the clinical features of tuberculous tumor of the brain and meningitis were present. There were no localizing symptoms. The patient had epileptic convulsions, and after an illness of one week died in coma. The spinal fluid was negative. At the autopsy a small abscess was found in the frontal lobe, which contained foul pus, in smears of which the streptothrix was found.

Dr. Flexner referred to a case similar to the first one which he had reported a few years ago from the Johns Hopkins Hospital. That case also strongly resembled tuberculosis, but the streptothrix was found on examination.

Dr. Abbott remarked that he had also encountered these organisms, and found some difficulty in distinguishing the condition from tuberculosis.

Dr. McPhedran gave an

EXHIBITION OF A URINARY SPECIMEN.

The specimen was obtained from a neurasthenic patient and was of a dark blue color. Chemical examination showed the coloring matter to be an indigo.

Dr. E. Trudeau presented a

REPORT ON A CHEMICAL STUDY OF THE TUBERCLE BACILLUS.

An assistant of Dr. Trudeau's recently started a chemical analysis of the tubercle bacillus and obtained some very interesting results. He found the organism to be composed of about 30% of wax, which is undoubtedly the part which takes up the stains. The outside coating consists of cellulose, and he also found three proteids from which he separated a nucleic acid. A coloring matter of light pink shade was obtained, and he was inclined to believe that the products of the nuclear proteid are the active portions of the organism. A glycogen was also isolated from the bacillus.

Dr. Vaughan described a

NEW FORM OF INCUBATOR.

devised for the purpose of cultivating enormous quantities of bacilli for chemical study.

AFTERNOON SESSION.

This session was called to order by the vice president, Dr. Wolcott.

Dr. Wm. A. Park, of New York, read a paper entitled

TO WHAT EXTENT IS URINE A SUITABLE SOIL FOR BACTERIAL GROWTH.

As the result of numerous tests it was found that the best growths occur in the neutral or slightly acid urines, but still there are certain urines that, without regard to the reaction, will not permit the growth of any bacteria. An effort was made to determine the amount of acid or alkali production by the bacteria. The colon bacillus made some alkali in albuminous urines. The staphylococci made more in diabetic urines, but the proteus made by far the most, changing some decidedly acid urines in a few hours into alkaline solutions. The practical bearing of this seemed to be that treatment might be aided in certain infections by keeping the urine decidedly acid.

Dr. F. P. Kinnicutt, of New York, read a paper on

ORCHITIS COMPLICATING TYPHOID FEVER.

Osler observed this complication in only 2 of his first 800 cases of typhoid, and Dr. Kinnicutt reported 2 cases occurring in 889 typhoid cases at the Presbyterian Hospital. Of the cases collected by Eshner, 35 occurred during the period of convalescence, and of these 13 went on to suppuration. Six presented on examination the Eberth bacillus, and only 1 the presence of any other pyogenic organism. Dr. Kinnicutt concludes that it is a rare complication of typhoidal origin, which develops late in the disease or during convalescence, and terminates usually by resolution. Suppuration occurs in 25% of all cases. Atrophy of the testicle is a rare sequence and death has not been noted.

Drs. Osler, Shattuck, Musser, Williams and Baumgarten all reported recent cases of this complication observed in their practices.

Dr. F. H. Williams, of Boston, presented

NOTES ON THE TREATMENT OF SOME FORMS OF CANCER BY THE X-RAYS.

He stated that the risk of producing burns is greater when using the x-rays for therapeutic than for photographic purposes, and their caustic action should be carefully guarded against. The cases he reported have all been examined by pathologists first to determine their cancerous nature. They consisted of epithelioma of the lid and hand and rodent ulcers. The cosmetic results were excellent. The treatment sometimes only requires a few exposures, and it can be conducted without the patient leaving off his usual occupation. The difficulties are that the apparatus is quite expensive and the treatment sometimes prolonged.

In reply to questions from Drs. Bond and Peabody he said he believed it was the x-rays and not the cathode rays which possessed therapeutic value, and that the interposition of a cloth or any penetrable substance between the patient and the tube made no difference in the action of the rays.

Drs. F. A. Packard and J. D. Steele, of Philadelphia, reported cases of

OSTEITIS DEFORMANS.

Dr. Packard analyzed the 67 cases from literature, showing the preponderance of this affection among males and its greater frequency in old age, together with the comparative infrequency of association with malignant tumors as contrasted with the usual text-book statements. He reported a case with the characteristic changes described by Padgett.

DR. WM. OSLER, of Baltimore, read a paper on

THE SPINAL FORM OF ARTHRITIS DEFORMANS.

He thought we should recognize clinically three different grades of this disease: (1) The form occurring in young children, characterized by enlargement of the spleen and lymph glands; (2) the form in adults characterized by atrophic changes; and (3) the more characteristic form with the well-recognized changes of the disease. Sometimes all the joints of the body are involved, and sometimes only a certain set of joints. He referred to one case in his care where only the feet and hands were involved.

He gave particular consideration to the form in which the spinal column is chiefly involved, and which has raised the question whether some of these cases are not due to diseases of the nervous system. He did not believe they were separate and distinct diseases, but looked upon them as a variety of arthritis deformans, differing only from the other types in involvement of the spine itself, some ligamentous tissue, and the posterior spinal nerve roots.

DRS. STOCKTON and LAMB exhibited

SKELETON SPECIMENS,

showing the bone changes, ankylosis, etc., that results from this affection.

DR. B. SACHS read a paper describing

CERTAIN TROPHONEUROSES AND THEIR RELATION TO VASCULAR DISEASE OF THE EXTREMITIES.

He reviewed a special group of trophoneuroses, heretofore generally believed to be due to changes in the nervous system, but in which careful examination of some cases had shown the trouble to have arisen in disease of the vessels rather than the nerves.

DR. J. J. PUTNAM, of Boston, gave

PERSONAL EXPERIENCES IN CASES OF JACKSONIAN EPIPLESY,

with special reference to the question of treatment by operation.

He considered this form of epilepsy to be the only one that warrants surgical intervention, and he advises it, although neurologists are more conservative on that point now than a few years ago. A focal lesion is not always found, but even in such cases operation frequently does good, perhaps through production of an inhibitory effect and the breaking of a vicious circle.

DR. F. FORCHHEIMER, of Cincinnati, read a paper on

THE HEREDITY OF APPENDICITIS.

The author reviewed at length the history of several families, and exhibited genealogical charts to show the number of cases occurring in certain families and their evident inheritance. The report was quite convincing, and in discussing the paper, DRS. BLACKADER and JACOBI reported other cases to show a similar family relationship.

THIRD DAY.

DR. E. L. TRUDEAU, of Saranac Lake, N. Y., read a paper on

THE IMPORTANCE OF A RECOGNITION OF THE SIGNIFICANCE OF EARLY TUBERCULOSIS IN ITS RELATION TO TREATMENT.

He reviewed the history of his work at the sanitarium and the work of others to show that tuberculosis placed under treatment in its incipiency will give about 75% of cures; whereas, if these same patients were allowed to waste their opportunities for treatment until the disease is well advanced, a fatal outcome or a prolonged illness is almost certain. He laid particular stress upon carefully investigating every case that shows a persistent, though irregular, afternoon rise of temperature of one-half degree or more. His experience has shown that the vast majority of patients seeking entrance to sanatoria apply too late to secure the best results, and he begged physicians in general to investigate their suspicious cases more closely, and to inform such patients of the nature of their disease so that they might secure proper treatment.

DRS. J. G. ADAMI and J. MCCRAE, of Montreal, read a paper on the

STUDY OF A SERIES OF CASES OF BURNS.

This experimental work agreed in every particular save one with that published by Bardeen, of the Johns Hopkins Hospital, several years ago. The authors did not find focal necrosis with the same regularity that Bardeen did, but the lesions were in all other respects similar to those of toxin infections.

AMERICAN SURGICAL ASSOCIATION.

ABSTRACT OF PAPERS AND DISCUSSIONS AT THE TWENTY-SECOND ANNUAL MEETING, HELD IN BALTIMORE, MD., MAY 7, 8 AND 9, 1901, THE PRESIDENT, DR. ROSWELL PARK, OF BUFFALO, N. Y., IN THE CHAIR.

FIRST DAY.— MORNING SESSION.

IMMEDIATELY after calling the meeting to order a short executive session was held, and then the scientific business was begun.

The president read his annual address, entitled

SOME PHASES OF THE CANCER QUESTION,

and stated that pathologists, who study the condition purely from the dead-house point of view, have confronted some of the greatest problems which it has to offer, but have also missed some of its most important aspects. The parasites of cancer, be their nature what it may, are in all probability polymorphic in extreme degree, and masquerade under many forms, changing with their different stages of reproduction. There is no other disease which is characterized by metastasis in which the pathologists decline to see evidences of parasitism. Every metastasis of cancer

has the form and significance of an inoculation experiment only performed under the most favorable, because natural, conditions. The primary question, after all, is the general one of parasitism, but it has not yet been reduced to a question of just what parasite. In the author's opinion, it may and probably will be found that cancer is not a question of any single organism, and possibly not even of a single class. The latest work of Roger Williams was then quoted at some length and reference was made to Demarquay, who collected 134 cases of cancer of the penis, whereas in only one instance was the wife affected with uterine cancer. Numerous cases are now on record of cancer along the track of the trocar used in tapping for ascites due to cancerous disease, and surgeons now quite generally admit this traumatic dissemination of the disease by inoculation of wounds during operations. From studies already made in the New York State Laboratory, it seems to be clear that death in cases of cancer comes about, as in so many other diseases, by a sort of terminal infection, which is a conspicuous feature of the disease, and has not hitherto attracted sufficient attention. The exact nature of these terminal changes has not yet been made out beyond what is implied in the term "hematogenous." The predictions of the Italians have failed in many respects, and it is by no means so easy to successfully inoculate animals with the yeast as has been generally supposed. By comparing tumors removed by operation with those removed post mortem, it became evident that the organisms either increased rapidly during the period just before death, or that they proliferate in the tissue immediately after death. In practically all scrapings from cancer could be seen either small hyaline refractive forms, which in suspension possess a characteristic oscillating motion, or larger forms with projecting pseudopodia, or sacular forms containing very refractive spherical bodies.

The work of Dr. Gaylord in association with the author was then referred to at considerable length, and reference was made to a number of publications by these gentlemen on this subject. It was mentioned that considerable difficulty is added to the work of investigation by the extraordinary polymorphism of many of the minute organisms found in cancer. Plimmer's work was referred to to a considerable extent, and deductions drawn therefrom. It appears that the protozoa are capable of producing in man lesions of widely different nature from mere infection of epithelium, and Pfeiffer has shown that they might produce them both in man and in animals. A full report was promised in a short time of the results of inoculating 72 animals with the technique employed.

Pfeiffer's work was quoted from at some length and various deductions were drawn therefrom.

That cancer begins as a purely local infection has been verified by the recent report by the author in the Laboratory at Buffalo, and also that it kills by becoming generalized, which is equally true of tuberculosis. Miliary carcinomatosis is not much more rare than miliary tuberculosis, and these constitute apparent exceptions to the above rule, but even they do not prove that the disease did not have a local beginning.

The author concluded his paper by stating, "I want to make it as evident as possible that carcinoma is an epithelial infection."

Dr. Thomas S. Cullen, of Baltimore, gave a lantern-slide exhibition of

THE EARLY SIGNS OF CARCINOMA OF THE UTERUS.

Dr. W. S. Halsted, of Baltimore, made a few remarks on a

BRIEF CONSIDERATION OF THE CASES OF CANCER OF THE BREAST TREATED AT THE JOHNS HOPKINS HOSPITAL SINCE 1889.

He spoke of the difficulties of getting a good picture of cancer, and stated that drawings are made in every case to file away with the records. He reported having operated on 320 cases of carcinoma of the breast and 450 cases of breast tumor, as well as 3 cases of primary sarcoma of the breast. Intracanalicular myxomata and fibromata are often spoken of as sarcoma, but in Dr. Halsted's opinion they are not. He referred at great length to the difficulty of compiling statistics, and demonstrated the method of grouping the cases at the Johns Hopkins in order to arrive at the proximate results. His experience is that the percentage of recurrences is very variable, and he reported that out of 129 cases operated upon 51 had been cured.

Dr. W. B. Coley, of New York, read a paper entitled

LATE RESULTS IN INOPERABLE SARCOMA TREATED WITH THE MIXED TOXINS,

and stated that he had secured the best results in cases of the spindle-cell variety. His results in the round-celled sarcoma have been fair, and sufficient to warrant further work along this line. The risks are *nil*, and out of 200 cases treated only 2 have died. He advised the use of the toxins in inoperable tumors only, and practically in sarcoma only. He reported no success in melanotic growths; but in lymphosarcoma of the neck, which are practically hopeless from an operative point of view, the toxins have a remarkable inhibitory effect. Out of 21 cases of spindle-cell sarcoma, 10 disappeared entirely, and 15 cases have passed the three-year limit, while eight years have elapsed in some cases since treatment. The author went into detail concerning a number of the cases in which the toxins were used, and stated that of the 15 who had passed the three-year limit 8 were of the spindle-cell variety and 2 were of the parotid gland. The results thus far, in the opinion of the author, are sufficient to warrant the use of the toxins when operations cannot be tried, and even in carcinoma they seem to have a marked inhibitory influence.

Dr. Joseph D. Bryant, of New York, read a paper entitled

THE INFLUENCE OF MENTAL DEPRESSION ON THE DEVELOPMENT OF MALIGNANT DISEASE,

in which he dwelt at length on the history of cancer as affected by mental depression. Paré, in 1510, was the first man to refer to mental perturbation, anger, and the like, as making a cancer "more fierce and raging"; while the same authority, under the head of treatment, insists that the patient must eschew fasting, watching, sorrows, cares and mourning. Sir Astley Cooper was of the same opinion, while Velpeau thought otherwise. Grant and Napoleon have been referred to as examples of cancer following reverses, and Paget and Virchow gave a qualified allegiance to the passive side of the question.

The foundations of the different phases of the contention rest on the beliefs (1) that cancer may result from the direct influence of mental depression; (2) that cancer may arise indirectly from mental depression because of the defective nutrition attendant upon it; and (3) that mental depression exercises in no respect influences that admit of sufficient proof to warrant serious discussion.

The author referred to the infrequency of cancer in insane patients, and stated that females suffered twice as often as males. Statistics were given from a number of institutions which showed that the death rate in the female was nearly double that of the male, although there were more male melancholics; but melancholia in the male does not seem to exercise any distinctive effect on the death rate. Neither is melancholia in the male more often associated with cancer than with other forms of malignant growths.

Many authors were quoted, and the following division of the cases was suggested: (1) Cases in which mental depression is not associated with the idea of cancer; (2) cases in which mental depression is associated with the idea of impending cancer of primary or secondary occurrence; and (3) cases in which the depression is the outcome of common causes.

AFTERNOON SESSION.

DR. J. COLLINS WARREN, of Boston, in discussing the foregoing papers, stated that there were several different ways of approaching the question as exemplified by different writers, and referred to the geographical, statistical, histological, experimental and blastomycetic. The experimental was divided into chronic irritation and inoculation, and reference was made to the fact that two papers had appeared during the year in favor of the protozoan theory of the disease.

Reference was made to the experiment of Lack in producing peritoneal cancer in a rabbit by scraping the ovaries, which observation, so far as known, has not been confirmed by other observers.

DR. CULLEN closed the discussion on his paper by stating that he had been very much interested in the report of the laboratory work at Buffalo. He commented at some length on Dr. Gaylord's experiments there, and made some reference to the lantern-slide picture shown by himself this morning.

DR. PARK stated that he had not told one-half of what he would like to tell, but promised another paper in a short time by Dr. Gaylord and himself, setting forth more fully the work that has been accomplished, particularly along the lines of inoculation.

DR. J. C. BLOODGOOD, of Baltimore, read a paper on

BLOOD EXAMINATION AS AN AID TO SURGICAL DIAGNOSIS,

illustrated by a large number of tables and statistics.

DR. J. C. DACOSTA, JR., read a paper entitled

THE CLINICAL EXAMINATION OF BLOOD IN APPENDICITIS: A STUDY BASED ON THE EXAMINATION OF ONE HUNDRED AND EIGHTEEN CASES IN THE GERMAN HOSPITAL, PHILADELPHIA.

The author discussed the subject under the heading of (1) methods and technique, (2) classification, and (3) the anemia of appendicitis. The details under each one of these headings was discussed at great length, and a large number of blood counts were given, both actual and comparative.

DR. J. B. BLAKE, J. C. HUBBARD and R. C. CABOT, of Boston, read a paper on

BLOOD EXAMINATION IN RELATION TO SURGICAL DIAGNOSIS,

and divided the subject into six headings: (1) The Leucocyte Count in Fractures; (2) Post-operative Leucocytosis; (3) Ether Leucocytosis; (4) the Effect of Fear on the Leucocytes; (5) Regeneration of the Blood after Operations on Malignant Tumors; and (6) Blood Examinations in Relation to Intestinal Perforation in Typhoid Fever.

DR. J. CHALMERS DACOSTA and DR. J. L. KALTEYER, of Philadelphia, read a paper entitled

THE EFFECT ON THE BLOOD OF ETHER AS AN ANESTHETIC.

The paper reviews the rather meagre literature of the subject, dwelling particularly upon the writings of Miculickz, J. Chalmers DaCosta, Oliver, Hamilton Fish, Bloodgood and others.

They dwell on the great difference of opinion which exists as to whether or not ether causes blood destruction. They hold that it does, and that those who affirm the contrary have been misled by the blood concentration which results from the preliminary treatment, and which is often added to by sweating during the anesthetic state. This blood concentration may mark the fall of hemoglobin; in fact, in some cases will cause an apparent rise. The important facts to note are that the color index practically always falls, and that the number of corpuscles increases. These facts prove marked blood destruction and increased production of corpuscles deficient in hemoglobin resulting from ether anesthesia. The authors report upon 50 cases, in which blood

examinations were made, and subdivide these cases into numerous tables for purposes of examination and comparison. In 49 of the cases the color index was lowered. The writers also showed sections of the marrow of a rabbit's femur, the animal having been etherized to death. These sections show marked erythroblastic proliferation.

The authors conclude that the hemoglobin is absolutely reduced after the administration of ether, this reduction being manifest in the individual corpuscular hemoglobin value. The increased hemolysis which occurs is nature's effort to rapidly replace the destroyed corpuscles and the regenerated cells are imperfectly supplied with hemoglobin. The authors urge that whenever possible one or two blood examinations should be made before ether is administered, and these examinations should be made before preparatory treatment has been instituted. If less than 50% of hemoglobin is present an anesthetic is dangerous, and should only be given in a surgical emergency which threatens life. In malignant disease a percentage of under 50 contraindicates operation. Miculickz says no general anesthetic should be given under any circumstances if the hemoglobin is under 30. We believe that 40% is probably the lowest justifiable limit. If operation must be performed when the hemoglobin is under 40%, a local anesthetic should be given, except under stress of absolute necessity. It is true, cases with under 40% of hemoglobin are occasionally etherized successfully (for instance, we know of one case with only 24%); but such instances are rare, are not sufficiently numerous to set aside the rule, and are only justified by the imperative necessities of a vital emergency. Whenever the percentage of hemoglobin is less, the administration of the anesthetic should be entrusted only to an experienced man; as little ether as possible should be given; the surgeon should operate quickly, and prompt measures should be adopted to bring about reaction and to remove the ether from the lungs and blood.

EXAMINATION OF THE BLOOD IN RELATION TO SURGERY OF SCIENTIFIC VALUE, BUT TOO OFTEN OF NO PRACTICAL VALUE, AND MAY MISGUIDE THE SURGEON,

was the subject of a paper read by DR. JOHN B. DEAVER, of Philadelphia. The author referred rather fully to the subject of appendicitis, and commented on the value of the microscope in bedside diagnosis, but objected to so much importance being attached to it as compared with the amount of weight given to other diagnostic points, some of which possess, in his opinion, greater merit as aids to the surgeon.

DR. B. FARQUHAR CURTIS, of New York, in discussing the foregoing papers, commented on the frequency of leucocytosis following ether anesthesia, and stated that this was equally true in intraspinal anesthesia. He believed that operative leucocytosis should be looked upon as a fixed factor, and one which could not be used in determining the existence of infection. He referred to a case as illustrating his point, and stated that while he considered the fact one of great value, he did not think it more so than the temperature and pulse record.

SECOND DAY.— MORNING SESSION.

This session was held at the Johns Hopkins Hospital, and addresses were made by DRS. OSLER and WELCH. Demonstrations were also given by DR. KELLY in the employment of the newer methods of diagnosis in rectal and urinary disease, and by DR. YOUNG in catheterization of the male urethra. Dr. Osler's remarks referred to the clinical and Dr. Welch's to the laboratory methods of teaching employed at the Johns Hopkins.

DR. OSCAR H. ALLIS gave a

DEMONSTRATION OF FRACTURES OF THE PELVIS.

He demonstrated upon the cadaver the effects of violence directed against the pelvis through the medium of the femur, being a comparative study of the relative strengths of the neck of the femur and that of the pelvis. The application of force was by means of a lever driving the head of the femur against the acetabulum, directed (1) at right angles to the long axis of the trunk, and (2) parallel to the long axis of the trunk.

AFTERNOON SESSION.

DR. A. W. MAYO ROBSON, of Leeds, England, read a paper entitled

PANCREATITIS WITH ESPECIAL REFERENCE TO CHRONIC PANCREATITIS.

The author commented on the fact that he thought it strange it had not until recently dawned on the minds of clinical observers that whatever obstructs the common bile duct at its lower end must also of necessity lead to an obstruction in the pancreatic duct. When the common bile duct is obstructed, the objective signs of jaundice at once demonstrate the fact; but hitherto no pathognomic sign has been discovered which will show conclusively that the pancreatic ducts are occluded, unless it be the extremely rapid loss of weight. When it is borne in mind that the prancreatic duct opens along with the common bile duct into the second part of the duodenum, it is not a matter for surprise that pancreatitis should be met with. The essential and immediate cause of the various forms of pancreatitis is bacterial infection, which has been positively proved both clinically in the human subject and experimentally in the lower animals. The association of gall stones with chronic pancreatitis was absolutely forced on his mind by the frequency with which he found inflammatory enlargements of the head of the pancreas when operating for gall stones in the common duct.

Taking up the subject of fat necrosis, it was stated that this condition is commonly found in association with pancreatitis, and the relationship

between the two conditions has given rise to much speculation.

Hemorrhage in pancreatic diseases was dwelt upon, and it was mentioned that death from collapse may occur either immediately or some hours after spontaneous hemorrhage. Several illustrative cases were cited, together with the symptoms and results, the following conclusions being reached: (1) that in certain diseases of the pancreas there is a general hemorrhagic tendency, which is much intensified by the presence of jaundice; (2) that hemorrhage may apparently occur in the pancreas unassociated with inflammation, or with jaundice, or with a general hemorrhagic tendency; (3) that both acute and chronic pancreatitis can and do frequently occur without hemorrhages; and (4) that some cases of pancreatitis are associated with local hemorrhage. It was suggested that pancreatitis should be divided into the acute, subacute and chronic, and that the hemorrhagic be considered a variety of the acute. The glycerine set free in the tissues by the fat necrosis was looked upon as a possible cause for the local hemorrhage, and some details on this point were gone into. In addition, the results of blood examinations, with a view of discovering, if possible, the cause of the hemorrhagic tendency, were given.

The treatment of the three stages of the disease was then discussed fully and examples given of each, together with the results of treatment, as well as of post mortems.

DR. GEORGE E. BREWER, of New York, stated that he believed the disease to be of far more frequent occurrence than is generally supposed, and in support of this assertion he cited the records obtained from the autopsy table, as showing its serious nature, frightful mortality and obscure symptomatology, as well as the fact that certain surgeons, as the author of the foregoing paper, have had a large personal experience with the disease, and where it has been extensively discussed a fairly large number of cases have annually been reported. The fact of its non-recognition by the profession at large is established by the fact that in other localities no cases are reported. He stated that in going over the recent annual reports of fifteen or twenty of New York's largest hospitals he found but one which recorded surgical treatment of the disease, and in this one institution four cases are reported as having been operated upon during a single year.

He believed the profession failed to recognize this disease more readily for two reasons: (1) Their attention has not been directed to it by reports of cases and monographs on the subject; and (2) sufficient data has not been collected on the subject for the compilation and presentation of an accurate and complete catalogue of the characteristic symptoms. He dwelt upon the importance of constant vigilance being maintained for this disease, and the value of recording and publishing the clinical histories and results of operations, together with the autopsy findings of all cases of this disorder coming under the surgeon's observation. This he felt would be of great value to the profession at large, enabling them to diagnose the condition much more readily. The anatomy of this region could be renewed with great interest, not only in regard to the clinical history and pathology of the disease, but might furnish some very valuable suggestions in reference to treatment. At a very early period in the development of the embryo, pancreas is formed by two offshoots from the intestinal tube, just below the gastric dilatation between the two layers of the posterior mesentery. These two branches rapidly develop, and again divide and subdivide, forming an innumerable number of fine twigs, each one ending in a small epithelial-lined sac. These are surrounded by minute plexuses of blood vessels, nerves and lymphatics, and held together by areolar tissue which divide the gland into a large number of segments or lobules. The further development of the pancreas was then discussed at some length, and the development of another outgrowth, which afterwards forms the liver, was noted. The different stages in the development of the bile duct and the two pancreatic ducts were recognized, and the fusion of the lower pancreatic duct with the bile duct, forming the ampulla of Vater, which opens into the duodenum in the adult subject, was remarked. He referred to the fact that the older anatomists taught that the upper pancreatic duct gradually atrophied, and only remained patent in a few instances; but later investigation resulted in the discovery that it could be injected from the main pancreatic duct in about 56% of the cases; and still later investigation by improved methods demonstrates the fact that the duct of Santorini is practically always present in the human subject.

He then presented five or six photographs furnished him by Dr. Carlton Flint, of the Anatomical Department of Columbia University, showing the arrangement and accessory in some of the lower animals as compared with those of the human body.

He then called the attention of the society to the fact that in the early stage of its development the pancreas is completely invested by the peritoneum, and only becomes a retroperitoneal organ by the absorption and conversion into areolar tissue and fat of the several layers of the posterior mesentery. The attention of the society was directed to the four different routes by which the pancreas may be reached; namely: (1) By dividing the gastrohepatic omentum just above the lesser curvature of the stomach; (2) by dividing the gastrocolic omentum just below the greater curvature of the stomach; (3) by dividing the transverse mesocolon; and (4) by reflecting the parietal peritoneum through a lumbar incision until the perirenal fat is reached, which is continuous with the areolar tissue surrounding the pancreas. He then mentioned the fact that in his opinion a probable causative relationship existed between an enlarged and relaxed duodenal orifice of the ampulla of Vater, due to the frequent passage of biliary calculi

and inflammatory diseases of both the bile duct and the pancreatic duct, stating that he based his opinion upon observations regarding the existence of like conditions in other portions of the body of ducts emptying into septic cavities in other portions of the body.

In concluding, he mentioned the probable digestive action of the pancreatic juice, when allowed to percolate into the connective surrounding the gland, as a cause of erosion of the blood vessels and extensive necrosis, in addition to the well-known power it possesses of producing fat necrosis.

Dr. Eugene L. Opie, of Baltimore, commented on the relation of gall stones to the disease under discussion. He considered that there are two mechanisms, which explain this association, due to the anatomical features of the region. As to acute hemorrhagic pancreatitis, he stated that a variety of irritating substances, when injected into the pancreas of animals, will produce this lesion, and referred to the experiments of Flexner, who had injected artificial gastric juice, acids, alkalies and dilute formalin, to prove the fact. Another cause of hemorrhagic pancreatitis he believed to be the penetration of bile into the pancreas, which will confirm the fact of the relation between pancreatitis and gall stones. It seems to be true that in the cases in which chronic interstitial pancreatitis accompanies gall stones in the common duct, the pancreatitis, which has been at times mistaken for malignant disease of the gland, is the result of this obstruction.

Dr. J. W. Elliot, of Boston, referred to the association of the disease with gall stones, together with the relation of jaundice to these conditions; while theoretically, if the common duct was not blocked, there would be no jaundice, yet practically, with stones only in the gall bladder, jaundice is frequently present. Cases were cited where these conditions were true, and where malignant disease had been diagnosed, although not present.

Dr. George R. Fowler, of Brooklyn, reported three cases with symptoms and treatment, two of which recovered, while the third died. He laid particular stress on the collapse which occurred in his cases, in one being so bad that operation had to be put off several times.

Dr. Carson, of St. Louis, gave the details of a case occurring in his practice, of induration of the pancreas associated with jaundice. After operation the patient made a good recovery.

Dr. W. L. Estes, of Easton, Pa., reported two cases of operation with recovery, one of chronic interstitial pancreatitis simulating carcinoma, and the other following an abdominal injury.

Dr. Leonard Freeman, of Denver, reported a case of jaundice, which he had believed to be due to gall stones, and stated it had not occurred to him that pancreatic disease was probably the cause, although he had no doubt such was the case.

Dr. Robson stated that he had never seen such marked and frequent attacks of collapse as those mentioned by Dr. Fowler. He reported one case where the collapsed condition of the patient had prevented operation, and death had ensued; and he believed that it was a common symptom, although not to the extent in individual cases observed by Dr. Fowler. He felt that the bile probably offered an explanation for many cases of hemorrhagic pancreatitis, and he believed the infected nature of the bile was often the most important factor. He referred briefly to Dr. Opie's specimens, and expressed himself as much pleased with Dr. Brewer's description of the anatomy of the region.

(To be continued.)

Recent Literature.

Thomas Sydenham. Masters of Medicine Series. By Joseph Frank Payne, M.D. (Oxon), Fellow and Harveian Librarian of the Royal College of Physicians. New York: Longmans, Green & Co. 1900.

This series contains, in addition to the present volume, John Hunter, William Harvey, Sir James Simpson, William Stokes, Sir Benjamin Brodie, Claude Bernard, Von Helmholtz, Vesalius; all Englishmen but three.

Sydenham's family was a Dorsetshire family, and in common with the well-to-do in that neighborhood its members were staunch Puritans and parliamentarians. His father, his uncles, his brothers and he himself were strenuous fighters for the Commonwealth. His oldest brother, Colonel Sydenham, who inherited the family property of Wynford Eagle, was one of the twenty persons, beside the regicides, named by the House of Commons, at the time of the Restoration, to be exempted from the benefits of the Act of Indemnity.

This little volume gives as full a sketch of Sydenham's life and character as can be had from existing and accessible materials, and at the same time throws vivid sidelights upon the important and stirring period of English history during which he lived. As a book, in common with others of this series, it is both interesting to read and useful to have.

Anatomie générale appliquée à la Physiologie et à la Médecine. Par Xav. Bichat, Médecin du Grand Hospice d'Humanité de Paris. Professeur d'Anatomie et de Physiologie. Première Partie. Pp. 256. Paris: G. Steinheil, Editeur. 1900.

This book is a reissue of Bichat's work, published as one of the volumes of the *Bibliothèque Positiviste*, and claims to be a reproduction of the edition of 1801, as regards orthography and punctuation. The book is naturally of interest to the student of the history of medicine, and to those who find profit in the presentation of gen-

eral facts in a philosophical spirit. It is always desirable that the work of the masters in natural science should from time to time be reprinted for the edification of later generations.

Consumption, Pneumonia and Their Allies. By THOMAS J. MAYO, A.M., M.D., Professor of Diseases of the Chest in the Philadelphia Polyclinic, etc. Pages 539. New York: E. B. Treat & Co. 1901:

This may fairly be called a picturesque book. The title itself carries a suggestion of belligerency, and the preface at once presents the author's ultimatum in the form of five propositions, which it seems worth while to quote in full.

(1) That pulmonary phthisis in the large majority of cases is primarily a neurosis, and that the pulmonary disintegration is secondary;

(2) That any agent, influence or condition which undermines the integrity of the nervous system will engender pulmonary phthisis, or some other form of pulmonary disorder;

(3) That the only remedies of value in the treatment of pulmonary phthisis are those which appeal to and act through the nervous system;

(4) That of special value in the treatment of phthisis is the counterirritant action of silver nitrate introduced hypodermically over the vagi in the neck;

(5) That acute pneumonia and other forms of acute pulmonary diseases are closely affiliated with disorders of the nervous system.

A further perusal of the book, however, shows that there is more reason in it than might be inferred. It presents evidence of great industry in the collating of cases having a bearing on the thesis, and the reader's interest must be stimulated by the suggestivenes of some of the evidence so ingeniously presented, even if at the end he still clings to the more commonly accepted theories of development. One feels that the author, if he had not tried to prove too much and had been less ambitious to see his views under the cover of a rather large volume, might have presented a very readable treatise. The outline of treatment is good, and in it the vaunted silver nitrate plays quite a subordinate part, as is doubtless right that it should.

The Feeding of Infants. Home Guide for Modifying Milk. By JOSEPH E. WINTERS, M.D., Professor of Diseases of Children, Cornell University Medical College. Pages vii, 47. New York: E. P. Dutton & Co. 1901.

This little book being, as stated in the title, merely a home guide for modifying milk, cannot be expected to give more than an outline of the principles of infant feeding. These, as far as they are given, are stated concisely and, on the whole, accurately.

Rules are given for the management of the dairy and for obtaining a clean, fresh milk. The author assumes that such an ideal milk is always obtainable, and gives no rules for pasteurization or sterilization, which he mentions only to condemn. As such ideal conditions are not always obtainable, and as pasteurization is therefore often a necessary evil, we feel that the author's position is a wrong one, and that the book would be improved if the method of pasteurization was described.

The author gives tables, based on a method of his own, for the preparation of modified milk at home from birth to one year. Tables showing the amount of food at a feeding and the intervals of feeding at various ages are also given.

The dangers of artificial feeding and the unsuitability of "infant foods" are clearly stated. This form of missionary work is extremely important and cannot be overdone. On the whole, this little book should be of much use to mothers and to many beginners in infant feeding, although it is decidedly rudimentary and adds nothing to our knowledge of the subject.

Diseases of the Heart. Their Diagnosis and Treatment. By ALBERT ABRAMS, A.M., M.D. (Heidelberg), F.R.M.S., Consulting Physician for Diseases of the Chest, Mt. Zion Hospital and the French Hospital, San Francisco. Chicago: G. P. Engelhard & Co. 1900.

The author somewhat disarms criticism by stating in the preface that "this little book was never intended to aspire to the dignity of a treatise on diseases of the heart," and states that "the primary object was to make it useful to the practical physician." He has undoubtedly compressed much information regarding the heart into its pages, which would, however, have carried more conviction if statements made in one place were not occasionally contradicted in another. For instance, on page 54 he speaks of the "small and irregular pulse of mitral stenosis," while on page 119 he says that it is "smaller in volume than normal, but regular"; and this is not the only instance. In an addendum he describes the "heart reflex," which is "practically a myocardial contraction consequent on irritation of the skin of the precordia by vigorous rubbing with the finger or, better still, by a spray of ether, and is manifest by the Röntgen rays and the fluoroscope." If corroborated, it will serve to explain the good results obtained in cases of dilated heart by the Schott method of treatment and by massage.

A Manual of Materia Medica and Pharmacology. Comprising all Organic and Inorganic Drugs, which are and have been official in the *United States Pharmacopœia*, together with Important Allied Species and Useful Synthetics. For Students of Medicine, Druggists, Pharmacists and Physicians. By DAVID M. R. CULBRETH, M.D., Professor of Botany, Materia Medica and Pharmacognosy in the Maryland College of Pharmacy, Baltimore. New (2d) edition. In one octavo volume of 881 pages, with 464 illustrations. Philadelphia and New York: Lea Brothers & Co. 1900.

This is a second edition of a book of decided value. The scope of the work has not materially changed over the earlier edition, and the original plan has been adhered to in the arrangement of

the comprehensive subject-matter, which is, as stated in the preface, "to associate as nearly together as possible those substances, organic and inorganic, which have a common or allied origin, allowing those next related to follow in regular order, the basal or parental source thus being kept paramount." Certain additions of new remedies and a fuller treatment of several departments of the subject, with an increased number of illustrations, are some of the changes in the new edition. The book is admirably printed, systematically arranged, and contains a vast amount of most important information.

Brubaker. A Compend of Human Physiology. Tenth edition. Philadelphia: P. Blakiston's Son & Co. 1900.

The use by a student of any short road to learning, such as a quiz compend, is to be regretted. Giving, as it should, only the outline of a science, the compend is of value solely as a review agent. But when a book is made to "represent the present state of the subject upon which it treats," it fails to be a help in review and acts as a shorter text book. As such the present work can not be compared in value with many of the text books in the market.

The present work, we are told in the advertisement, is "based upon the most popular text books." To even the uncritical reader it is evident that the book is not the systematic thought of one man. Although the work is in the tenth edition, the author has not taken sufficient care in systematizing the statements gathered from various sources. The indiscriminate use of the English and the metric systems of measures — the inch, the line and the millimetre, the gram and the ounce, Fehrenheit and Centigrave determinatives — tends to make the student unsystematic in his thinking.

Sensory and *sensitive* are not usually considered to be synonymous with the the term *pain*, as the author leads the reader to believe (see pages 83, 84, 183, etc). Figure 1 is unnecessary for a medical student and may be misleading to others. Space is lacking for a detailed criticism of the material contained in the work; but if an eleventh edition should be called for — the reviewer hopes it will not — the student might be informed (1) of the functions of the white blood corpuscles; (2) of the relation of the blood to the carrying of CO_2; (3) of the interchange of gases between the tissues and the blood, namely, internal respiration; and (4) of the view of Goltz and others regarding the functions of the cerebral cortex.

In the attempt to make the book "pocket size," while still retaining all the facts, the publishers have resorted to the use of small type.

Opening of New Wards at Newton, Mass., Hospital. — In recognition of the completion of the contagious wards of the Newton Hospital, a reception and inspection of the additions to the hospital's equipment was made last week.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 13, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

SOME STATISTICS OF CANCER.

Any facts bearing upon cancer in any of its aspects is of special interest at the present time, owing to the renewed zeal which is being manifested both abroad and in this country in the attempt to discover its cause. Now that the diagnosis of carcinoma may be made with practical certainty by means of the microscope, it is evident that statistics have a value and significance which could not be claimed for them a few decades ago. A paper by Dr. E. N. Nason, published in the *British Medical Journal* for May 18, 1901, on an analysis of 5,000 cases of death from malignant disease, is of unusual interest as a statistical study. The facts were collected in the course of preparation of a report for the British Medical Association on the influence of locality on the prevalence of malignant disease, and expanded with conclusions, for the purposes of the present paper. Dr. Nason found what we have come ordinarily to expect, that the preponderance of females over males as subjects of cancer was about 62 to 38%, due to the fact of the great frequency of uterine and breast involvement. The writer feels justified in looking upon the excess of female cases as dependent upon the fact that women are the possessors of these two organs, rather than as an indication of their generally greater tendency to cancer. If the sexual peculiarities of both sexes be excluded, the male is found to be the more often affected in the proportion of 53 to 47%. It furthermore appears that the steady increase of mortality from cancer which has occurred during the last thirty years, has been far more noticeable in men than in women. This is explainable in part by the greater accuracy of diagnosis of cancer in internal organs other than the uterus, to which men are as liable as women, and to the fact that surgical measures have reduced the mortality among women from the two most frequent varieties:

cancer of the breast and uterus. Men also are more exposed to the influences of trauma and syphilis, which Dr. Nason regards as important predisposing causes.

The general conclusions which the investigating committee reached are as follows:

1. Certain more or less well-defined areas exist in which the mortality from cancer is markedly above, and others in which it is markedly below, the average for England and Wales.

2. Although age and sex incidence undoubtedly influence this variation, in some cases considerably, they only account for a small proportion of it.

3. That owing to the great difficulty of diagnosis in many cases of internal cancer, the death-rate from cancer is probably at present underestimated.

4. Contamination of the soil or subsoil for long periods with decomposing organic matter is very probably a factor in the production of a high death-rate from cancer.

5. A damp, ill-drained, waterlogged soil of whatever geological formation, is more frequently associated with a high cancer death-rate than is a dry, well-drained soil.

6. There is abundant evidence of the existence of groups of houses in which cancer is found with marked frequency; and some evidence which tends to show that second and third cases occur in the same house with greater frequency than can be accounted for by mere coincidence.

7. Cancer occurs more frequently in old than in new houses and districts.

8. There is some evidence suggesting that under certain circumstances cancer may possibly be transmitted from one person to another in constant close association.

As some of the more certain predisposing causes are given: prolonged local irritation, the effects of direct and sudden injury, syphilis and possibly other constitutional diseases, the tissue degeneration of advancing years, and the presence of fetal remnants. As an exciting cause Dr. Nason thinks a parasitic organism would best explain the facts, but naturally, in the present state of our knowledge of this intricate subject he has no evidence of value to offer in support of this proposition.

We would commend this paper to those interested in collecting and tabulating statistics of this increasingly fatal disease. As in all statistics there are no doubt many sources of error, but it represents a type of laborious work which is of very great value in the solution of many vexed questions regarding the growth and spread of cancer.

ONE HUNDRED AND TWENTIETH ANNIVERSARY OF MASSACHUSETTS MEDICAL SOCIETY.

WITH venerable and increasing age the Massachusetts Medical Society shows no signs of decrepitude, no indications of waning vigor. On the contrary, its members are constantly increasing, and its work, as shown in its annual meeting just terminated, may easily challenge comparison with any period of its past history. The attendance has been large from all parts of the State, and the interest manifested in the general session, notwithstanding the absence of several papers which had been promised from different bacteriological laboratories, in the Sections of Medicine and Surgery, the Shattuck Lecture and the Annual Discourse, was most emphatic. There were no excursions, no exhibits, no junketting, and yet the whole time of all in attendance has been at once most profitably and agreeably occupied. Much of this is due to the good work of the officers, the committee of arrangements, and those entrusted with the various programmes.

The new Medical Library Building has added much to the comfort, convenience and pleasure of the occasion, and the same should be said of the use for larger meetings, and for the annual dinner of Chickering and Symphony Halls. At least an appreciative word must be added in praise of the singing of the Graduates' Glee Club at the annual dinner. This organization, under the direction of Dr. Sumner Coolidge, has reached a high degree of proficiency, and furnished music in grateful contrast to the band of former days.

A PROPOSED MEMORIAL TO JESSE WILLIAM LAZEAR, M.D.

IT will be remembered that in September of last year Dr. Jesse William Lazear, at that time acting assistant surgeon in the United States Army, and a member of the government commission for the investigation of yellow fever, contracted the disease of which he was making a study, and died at Quemados, Cuba. The circumstances under which he met his death were peculiarly heroic, since he voluntarily submitted himself to the experiment of being bitten by an infected mosquito, in the attempt to gain evidence that the affection is transmitted in this way. Dr. Lazear was still young and a man of very great promise. He was a graduate of Johns Hopkins University and received his degree in medicine at Columbia. He later studied in Europe and at the Johns Hopkins Hospital, and until his appointment to the army was engaged in teaching and research at that institution.

The friends of Dr. Lazear have felt that a lasting memorial should be established to him and to his work. To this end a circular has been sent out by a committee, of which Dr. William Osler is chairman, in the hope and with the expectation that a sufficient amount may be raised to procure an adequate memorial. We quote a part of the circular: "The many friends and admirers of the talented and accomplished student, of the brave, true, self-sacrificing man, desire to estab-

lish a lasting memorial to him and to his work. To this end a meeting was held on the evening of Wednesday, May 22d, which was presided over by Prof. William Osler. At this meeting it was concluded that the nature of the memorial could better be decided upon when some idea could be obtained as to the amount of money available. It was therefore decided that a committee, consisting of Dr. Stewart Paton and Dr. William S. Thayer, be appointed to arrange for the distribution of a circular among the friends and admirers of Lazear, setting forth the object of the meeting. It is earnestly hoped that not only those who have known and admired Lazear and his work, but also others who appreciate courage and manliness and self-sacrifice, may contribute to the fund for the Jesse William Lazear Memorial. Subscriptions may be sent to Dr. Stewart Paton, treasurer, Johns Hopkins Hospital, Baltimore, Md."

We are in entire accord with the spirit of this movement, and hope that the prompt reply to the circular from a sufficient number of subscribers may quickly make possible its consummation. Memorials are founded for various purposes, but we are disposed to think that the quiet devotion to duty which marked Dr. Lazear's death is far more worthy of such a recognition than many more ostentatious achievements.

A REORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

At the meeting of the American Medical Association in 1900 a Committee on Organization was appointed. This committee presented its report at the recent meeting of the association at St. Paul, and the report, including the revised Constitution and By-Laws, on motion of Dr. Harris, of New York, was adopted by a large majority. The report itself is a lengthy document, for the full text of which and for the report on the revision of the Constitution and By-Laws our readers are referred to the Journal of the Association, the issues for May 11th and June 8th. The necessity for these changes has long been apparent. Under the old conditions the transaction of business was either difficult or impossible, or so easy that it was undesirable. The association itself had not the weight in professional and public affairs to which its members and wide representation should entitle it.

The association has now provided itself with a more suitable machinery with which to work, but the results attained must depend in large measure upon the cordial co-operation of the State and county societies, a co-operation which we hope may be in due time forthcoming.

MEDICAL NOTES.

Appointment of William R. Stokes, M.D. — Dr. William Royal Stokes, city bacteriologist of Baltimore, has been appointed to the chair of pathology in the College of Physicians and Surgeons in that city.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, June 12, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 74, scarlatina 26, measles 181, typhoid fever 4, smallpox 0.

Smallpox in Various Places. — Two physicians of Worcester, Mass., who had been in attendance on a patient in the hospital suffering from smallpox, have contracted the disease. In Berlin, N. H., there are said to be 42 cases in the pesthouse. The malady is, however, of a mild type, but one death having occurred, and then because of other complications. A Portuguese schooner recently arrived at New Bedford from the Azores, with a large number of cases of smallpox on board. The vessel's passengers and crew will be cared for at the quarantine station on Gallop's Island, Boston Harbor, until danger of a spread of the disease from this source is past. It is said that the Boston health authorities have undertaken to care for the vessel's people, in accordance with an arrangement between that body and the surgeon-general of the navy, and all expenses will be paid by the vessel's owners. Objection is, however, made to taking patients who have been landed from the vessel. Fifteen cases of the disease are reported as under observation in the neighborhood of Providence, R. I., chiefly of a mild type.

A Queer Job for a Board of Health. — The Legislature of the Commonwealth of Massachusetts has ordered that the State Board of Health make a scientific and thorough physiological investigation of the healthfulness of baking-powders, making such tests as will demonstrate whether or not any brands of baking-powder on sale in this commonwealth are prejudicial to health, and whether the introduction into food of an article in small quantities, which ordinarily would be harmless, would, when taken by a person in feeble health or dietetically disordered, eventually undermine the system; and that said board make such recommendations to the next General Court as the result of said investigation shall in its opinion warrant.

A Proposed Hospital for Infectious Diseases in Cambridge, Mass. — Acting on a recent suggestion of Mayor Dickinson, of Cambridge,

the committee on health of the city council has negotiated for land on Concord Avenue, near the Belmont line. The lot is large enough to provide for a building for infectious diseases, a building for smallpox cases,— should the occasion arise,— for a diphtheria hospital, and for a general hospital. It is understood that the town of Belmont will coöperate with Cambridge in the maintenance of such an institution.

BOSTON FLOATING HOSPITAL. — The first trip of the Floating Hospital will take place July 5th. It will cost about $20,000 to operate the hospital for the summer. Several changes have been made in the medical staff. Dr. J. H. Pratt, of Harvard Medical School, has been appointed pathologist, and Dr. A. W. Fairbanks assistant to the visiting staff. There will be two resident physicians and two assistant resident physicians. There are, in addition, seven medical assistants.

A SERIOUS FIRE AVERTED IN THE CAMBRIDGE, MASS., HOSPITAL. — A fire started in the basement of the Cambridge Hospital the latter part of last week from the explosion of a tank of kerosene, but was checked by the prompt action of the fire department. No patients were injured, and the total damage is estimated at not more than $500.

NEW YORK.

A CASE INVOLVING THE CHILD-LABOR LAW.— Louis Lehmaier employed Vito Marino, a boy of twelve years, to run a machine in a factory, in violation of the labor law prohibiting the employment of children under fourteen years of age in factories. The boy had his fingers caught in the machinery, was injured, and sued for damages. The case was lost and appealed, and the Appellate Division of the Supreme Court has now given the following opinion on it: "If the defendant had complied with the statute and had not employed this child in his factory, the injury would not have happened; and thus placing the child at work upon a machine in violation of the statute, was the proximate cause of the injury. There was a case for the jury as to the defendant's negligence, and the judgment appealed from should be reversed and a new trial ordered."

ADDITIONAL PRIZES AT COLUMBIA.— At the monthly meeting of the Board of Trustees of Columbia University, held June 3d, it was announced that as a result of a considerable increase in the value of the prize fund founded in the College of Physicians and Surgeons by Dr. Jacob Harsen, of the class of 1825, three additional Harsen prizes, of $500, $300 and $200 respectively, have been established for proficiency in examinations. Among the gifts reported was one of $1,500 for fitting up the zoölogical laboratory in Barnard College. Drs. Charles H. Peck, Warren S. Bickham and Alfred S. Taylor have been appointed assistants in surgery in the medical department.

UNIVERSITY OF NEW YORK.— The sixty-ninth annual commencement of the professional and graduate schools of the University of the City of New York was held on June 6th at the Metropolitan Opera House. There were 74 graduates in medicine and 6 in veterinary surgery, and it was announced that 32 of the former had secured hospital appointments. Among the announcements made by the chancellor was that Dr. Robert MacDougall, of Harvard, had been appointed to the chair of experimental psychology in the School of Pedagogy.

DEPORTATION OF TUBERCULOUS IMMIGRANTS.— Commissioner-of-Immigration Fitchie, who has just returned from a visit to Washington, reports that the recent order requiring the deportation of all immigrants affected with tuberculosis is simply the result of a ruling on the matter which had been asked for by the Marine Medical Service. The order classes tuberculosis as a "dangerous contagious disease."

Miscellany.

AMERICAN SOLDIERS IN THE TROPICS.

ON May 31st at the Association of Military Surgeons at St. Paul, Minn., Dr. Louis L. Seaman of New York, late Surgeon First United States Volunteer Engineers, who has recently returned from China, read a valuable paper, in the course of which he said: It is interesting to note that on their arrival in China it was the boast of the medical officers of the German Army that typhoid fever and dysentery were comparatively unknown visitors to their camps. Yet within two months their hospitals contained over 500 cases of typhoid, followed by an appalling list of fatalities, while the wards of the American hospitals were and are still singularly free. The Americans had the only water-distilling plant in operation in Pekin, and its capacity was so much greater than the requirements of our army that two tons of the surplus water were donated to the Japanese every day of the winter. The American quartermaster also cut and stored 800 tons of ice in Pekin — the only ice ever housed in that ancient city. The low percentage of all illnesses except those of a private nature, and especially the almost total absence of the class termed "digestive diseases," offers a startling contrast to conditions existing during the Spanish-American war in Porto Rico or Cuba. There I have seen as high as 75% of a command suffering from these diseases at one time, and in the Philippines the percentage of these cases remains persistently high. One nat-

urally looks sharply for the cause of this startling difference, a difference of from one two-hundredth of 1% to 75%. Here in this invigorating zero temperature, where animal heat is rapidly radiated, the men show evidences of splendid health. In China heat-producing foods are needed. Even our full army ration, the richest and most varied in the world, and the envy of every soldier in the allied armies, was not found sufficient to satisfy the cravings of the men. The energy of their systems was not consumed in an effort to eliminate heat-producing foods, as was the case when they were in the tropics, where such foods were superfluous or inappropriate, and therefore not digested or metabolized. Under these conditions such foods rapidly undergo decomposition in the intestinal tract and create toxins, which nature endeavors to eliminate as quickly as possible by establishing catarrhs and diarrhea as the only method left to rid herself of such irritants. And yet Congress has just decreed that no change shall be made in the United States Army ration—that it shall remain practically the same at the pole as at the equator. Let it not be forgotten that in the Spanish-American War, the actual hostilities of which lasted but six weeks, there were fifteen fatalities from disease (practically all preventable) for every one from bullets and wounds. If any vindication were necessary for the theory of regulating the ration of an army to suit climatic conditions, unanswerable proof can be found in Pekin in the study of the statistics of every company serving in the Chinese expedition.

INVESTIGATION OF TUBERCULOSIS IN NEW YORK STATE.

IT having been announced that the State Department of Health is about to take an enumeration of the persons in New York State affected with tuberculosis, Commissioner Daniel Lewis has given out the following statement: "The present immediate purpose is not to require or obtain a personal registry of these cases, nor to institute a system of sanitary inspection or isolation of consumptives, but to obtain, with such accuracy as it is possible to do, a record of the number of persons in each municipality who at this time are subjects of this disease; to learn the locality of the disease, its distribution and surroundings. This accumulation of data will be fundamental to more exact plans for its control. It will likewise be of great value in the discussion of the question of State care of consumptives, and also in determining the death rate from this cause. A further report of the sources of infection would also be valuable in the study of the etiology and prophylaxis of tuberculosis. We are not inaugurating a new work, for since 1893 something in this direction has been in operation." In a special report by Dr. H. M. Biggs, of the City Health Department, which was introduced in the recent report of the Tenement-house Commission, it is pointed out that more than one-quarter of all deaths occurring in New York City in the period of greatest usefulness — fifteen to sixty-five — are due to tubercular disease; and the opinion is expressed that with the enforcement of certain regulations, especially regarding tenement houses and lodging-houses, and the immediate municipal provision of hospital accommodations for from 2,500 to 3,000 consumptives, the death rate in the city from tuberculosis would within five years be reduced by one-third — a saving annually of 3,000 lives.

DERMATITIS PRODUCED BY A CATERPILLAR.

BOSTON, June 10, 1901.

MR. EDITOR: — Last summer I saw at the clinic for skin diseases at the Massachusetts General Hospital a considerable number of cases of inflammation of the skin, which were undoubtedly caused by contact with some caterpillar. The dermatitis was of the same type in all the cases, and there was also a uniform history of the removal of caterpillars from the affected parts just preceding the appearance of the eruption. As such cases had not previously occurred under my observation, I concluded that the larva must be some recently-introduced species. The parts affected were generally the neck, sometimes the face and hands. The efflorescence was urticarial in character, but very persistent; that is, remaining unchanged for two or three days. The lesions were in some cases arranged in long, continuous tracts, as if following the course of the creature upon the skin. The statements generally given were that the patient had been walking, or had sat under a tree, and had found the caterpillar crawling over the parts which were affected a few hours later.

This season several patients have already presented themselves with the same peculiar, persistent itching, more or less confluent, urticarial eruption chiefly upon the neck (two of them today), and tell the same story. They all give the same description of the caterpillar, which is probably the larva of the brown-tailed moth, *Euproctis chrysorrhea*. The patients come from towns in this vicinity. The affection yields quickly to soothing washes.

Yours very truly,

JAMES C. WHITE, M.D.

METEOROLOGICAL RECORD.

For the week ending June 1st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 1,989, under five years of age 602; principal infectious diseases (smallpox, measles, scarlet fever, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 528, acute lung diseases 265, consumption 262, scarlet fever 46, influenza 2, erysipelas 14, typhoid fever 19, whooping cough 7, measles 20, cerebro-spinal meningitis 8, smallpox 17.

From whooping cough, New York 4, Baltimore, Pittsburg and Boston 1 each. From cerebro-spinal meningitis, New York 4, Baltimore, Boston, Somerville and Gloucester 1 each. From scarlet fever, New York 38, Pittsburg 1, Boston 6, Everett 1. From typhoid fever, New York 2, Pittsburg 11, Boston, Fall River, Cambridge, Taunton, Everett and Beverly 1 each. From erysipelas, New York 10, Baltimore, Pittsburg, Boston and Lowell 1 each. From influenza, Baltimore and Pittsburg 1 each. From smallpox, New York 17.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,463,187 for the week ending May 18th the death rate was 16.8. Deaths reported 3,689: acute diseases of the respiratory organs (London) 249, whooping cough 150, diphtheria 45, measles 81, fever 16, scarlet fever 31.

The death rate ranged from 8.9 in Croydon to 22.1 in Preston; Birkenhead 15.5, Birmingham 19.1, Blackburn 18.8, Bolton 18.8, Bradford 17.3, Brighton 12.6, Bristol 16.9, Burnley 18.2, Cardiff 14.2, Derby 17.2, Gateshead 15.1, Halifax 19.8, Huddersfield 14.3, Hull 16.7, Leeds 17.6, Leicester 12.8, Liverpool 20.0, London 15.8, Manchester 20.7, Newcastle-on-Tyne 15.7, Norwich 14.4, Nottingham 17.6, Oldham 14.0, Plymouth 16.9, Portsmouth 15.1, Salford 19.1, Sheffield 15.8, Sunderland 22.0, Swansea 19.8, West Ham 16.7, Wolverhampton 16.6.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, WEEK ENDING JUNE 1, 1901.

DR. J. H. IDEN, appointed assistant surgeon in the Navy, from May 4, 1901.

W. S. DIXON, medical director. Commissioned medical director from April 28, 1901.

C. G. HERNDON, medical inspector. Commissioned medical inspector from April 28, 1901.

E. V. ARMSTRONG, passed assistant surgeon. Detached from "Vermont" and ordered to Key West Naval Station for duty at Dry Tortugas.

T. M. LIPPITT, assistant surgeon. Ordered to the Washington Navy Yard, June 1st.

R. B. WILLIAMS, assistant surgeon. Detached from duty at Dry Tortugas, and ordered home to be in readiness for sea duty.

J. H. IDEN, assistant surgeon. Ordered to Naval Hospital, Chelsea, Mass., for duty.

J. F. COSTIGAN, passed assistant surgeon. Detached from the "Yorktown" and ordered home. Resignation to be accepted after arrival.

W. M. GARTON, assistant surgeon. Detached from the Washington Navy Yard, June 1st, and ordered to the "Indiana."

H. O. SHIFFERT, assistant surgeon. Ordered to the "Nashville."

E. THOMPSON, assistant surgeon. Ordered to the "Solace."

R. K. MCCLANAHAN, assistant surgeon. Ordered to the "Culgoa."

J. COWAN, pharmacist. Detached from the Manila and Cavite Naval Station and ordered to Naval Hospital, Yokohama, Japan.

SOCIETY NOTICES.

BRITISH CONGRESS ON TUBERCULOSIS. — The British Congress on Tuberculosis will be held in the Queen's Hall, London, from Monday, July 22, to Friday, July 26, 1901, under the patronage of the king.

BOSTON MEDICAL LIBRARY. — The Medical Library will hold its first Smoke-talk June 15th, at 8.15 P.M., at the Library Building, 8 The Fenway. Dr. C. J. Blake will give a short talk. Dr. Malcolm Storer will show and talk about some of the Library's collection of medical medals. Dr. J. W. Courtney will read a sketch entitled "The Journalistic Physician." There will be singing by members of the Harvard Graduates' Glee Club.

F. J. COTTON, M.D., Chairman of Committee.

RECENT DEATH.

SETH B. SPRAGUE, M.D., of Jersey City, N. J., died on June 5th, after an extended illness. He was born at Dexter, Me., January 12, 1840, and was a graduate of Bowdoin. His eldest son, Dr. Ezra K. Sprague, is a passed assistant surgeon in the United States Marine Hospital service.

A STUDY OF THE FOOD CONSUMED AND DIGESTED BY FOUR MEMBERS OF THE HARVARD UNIVERSITY BOAT CREW IN JUNE, 1900.

BY W. O. ATWATER AND F. G. BENEDICT,
MIDDLETOWN, CONN.

INTRODUCTION.

CONSIDERABLE information has accumulated within the past few years concerning the normal and usual food consumption of mechanics, laboring men, professional men and other people in ordinary conditions of life, but the food requirement of athletes is less definitely understood.

In Bulletin No. 75 of the Office of Experiment Stations of the U. S. Department of Agriculture,[1] account is given of dietary studies carried on with the Harvard and Yale University boat crews during the spring of 1898. These show the kinds, amounts and composition of the food actually eaten by the crews, and in one instance by an individual member, when in training at Cambridge and New Haven, and later at Gales Ferry, near New London. Another bulletin of the same department, now in press, reports the kinds, amounts and composition of the food eaten, and the amounts and composition of the feces and urine excreted by three bicycle racers during a six-day race in Madison Square Garden, New York City.[2] The studies just mentioned, with one of the food eaten by Sandow,[3] one of food eaten and urinary excretions by Weston, the pedestrian,[4] and two of food eaten by college foot-ball teams, one at Wesleyan,[5] and one at the University of California,[6] represent practically the extent of the investigations of the food of athletes thus far made in this country. A few investigations of a somewhat similar nature have been made in other countries.

It is evident that more data are needed regarding the food consumption and food requirements of persons with intense muscular exercise. The desired information is ordinarily sought by dietary studies, digestion experiments, studies of the excretory products,—especially the urine, nitrogen metabolism experiments, and, finally, respiration and respiration calorimeter experiments, which include more detailed investigation of the metabolism of matter and energy in the body.

Dietary studies.— The object of studies of this sort is generally to find the kinds, amounts and composition of the food consumed by people of different classes. A large number of dietary studies of people in ordinary walks of life have been made in this and other countries, but the number made with athletes is still small, as just explained. The investigation here reported includes such a study.

Digestion experiments.— Not all of the food consumed is actually available to the body for the building and repair of tissue and the yielding of energy. A portion resists the action of the digestive juices, and is eliminated, together with residues from the digestive juices and other metabolic products, in the intestinal excreta. The proportions of the nutrients of the food which are actually available to the body have been determined by means of so-called digestion experiments, in which the ingredients of the food eaten and those excreted in the feces are compared, in order to find the proportion thus actually used by the body. A large number of experiments of this sort have been made with people engaged in ordinary occupations. Very few data, however, have accumulated concerning the relative digestibility of the same food materials under different conditions of rest and of more or less active or severe labor. The present investigation includes a digestion experiment under conditions of very severe muscular work.

Investigations of excretory products.— The composition of urine is one of the most, and that of feces one of the least, thoroughly studied topics of physiological chemistry. In the present experiments the feces were analyzed by the methods commonly followed, while the examinations of urine were somewhat more detailed than are usual in digestion experiments.

Nitrogen metabolism experiments.— The object here is the study of the metabolism of proteids, as shown by the income and outgo of nitrogen. In the present experiments the total nitrogen was determined in the food, feces and urine, thus showing the nitrogen balance.

THE INVESTIGATION.

The present investigation, which thus includes dietary, digestion and nitrogen metabolism experiments,[7] was made at the instigation of the Harvard Athletic Committee, through Dr. E. A. Darling in order to obtain information regarding the food consumed and digested by the Harvard University boat crew. The observations were made in June, 1900, at the headquarters of the crew, at Gales Ferry, near New London, during the last days of training previous to the race with Yale, on June 28th. The feces and urine were sent, with samples of the food materials, to Middletown, where the analyses were made in the chemical laboratory of Wesleyan University.

[4] Reported by Austin Flint in New York Medical Journal, June, 1871.

[5] Reported by W. O. Atwater and C. D. Woods in Storrs' (Conn.) Agricultural Experiment Station Report, 1891, p. 128.

[6] Reported by M. E. Jaffa in Bulletin No. 84 of the Office of Experiment Stations of the U. S. Department of Agriculture.

[7] The experiments were so planned as to bring them in line with a larger inquiry regarding the food and nutrition of man, which is being carried on by authority of Congress, under the auspices of the Department of Agriculture, and by co-operation with a considerable number of universities, colleges, and experiment stations in different parts of the country. The extent of the present investigation, its usefulness for its especial purpose and its general value are thus greater than would otherwise have been possible. Its relation to the larger inquiry will account for the numbering of the dietary and digestion experiments in the tables beyond, as well as the fact that the results of that inquiry have been drawn upon so freely. The details of the experiments will probably be published in a bulletin of the Office of Experiment Stations of the U. S. Department of Agriculture.

Subjects.— It was not practicable to include all of the crew in the study, but it was possible to make such arrangements with four members of the crew, that their exact food consumption could be determined, as well as the quantities of liquid and solid excreta. The ages, heights and weights of the four men were as follows:

Subject.	Age. Years.	Height. Feet.	Inches.	Weight. Pounds.
A	30	6	2 1-2	174
B	22	5	11	163
C	19	6	0	175
D	25	6	1 1-2	167

Physical condition of the men; daily routine. — As regards the physical characteristics and condition of the men, it will suffice here simply to call attention to the fact that they were in normal condition throughout the period of the study. The men rose at 7 A.M. and took a five-minute walk before breakfast. After breakfast they indulged in reading, going out in the launch, playing games, etc., until about ten o'clock, when they prepared for morning practice on the river, which was in general from three-quarters to one and one-quarter hours in duration. On the return, after the bath a light lunch was served, and at two o'clock a heartier meal was taken. The evening row began between five and six o'clock, and lasted from one-half to two hours. The last and the heartiest meal of the day was served about eight o'clock, and at its close the men sang or read until ten o'clock, at which time they were obliged to retire.

General plan of the study.— The four men ate at a small table in the large general living room, which served as a dining room. The remainder of the crew, the substitutes and the coaches, sat at one long table in the same room. The observers in charge of the investigation were stationed at the door of the pantry adjoining. The small table, at which the men under observation sat, was served by a special waiter, who was also required to serve, in a general way, at the large table. Each article of food served at the small table and all food materials taken from that table were weighed, and samples were taken for analysis. No attempt was made to determine the proportions of food consumed by the four men individually. The study began with breakfast Tuesday morning, June 19th, and ended with the evening meal of Monday, the 25th.

Food.— The kinds of food materials served were much the same as those in the study of Harvard crews two years previous, the results of which have already been referred to.[8] All the visible fat was trimmed from the meat, and rejected. With lamb or mutton chops only a small amount of the total weight of the chop was actually eaten. Well-cooked, crisp bacon was served occasionally, and seemed to be especially relished. Most of the bread was toasted, although at the last meal of each day stale bread was allowed. A dish of calves' foot jelly with sherry was given after the morning row, and at the evening meal ale or claret was allowed. It was noticed that after the time row, and other unusually severe work, more ale or claret was taken. Table 3 beyond shows the kinds and amounts of food materials consumed.

Feces.— In collecting the solid excreta from a given diet it is customary to make the separation between the feces from the diet under consideration and those from the previous and subsequent diet, by means of small portions of charcoal administered at the beginning and end of the experiment. The charcoal serves to color the feces. Such separation was attempted in this investigation; but owing to a misunderstanding the feces were not collected after the close of the study, and consequently the final separation was not obtained, and the first was of no use. In order to provide in advance for such a contingency the feces excreted by each subject were collected for each day, beginning with the commencement of the experiment, and thus the feces eliminated during the exact period covered by the study were taken as the measure of the feces belonging to the food eaten during the same period. Inasmuch as the diet was very nearly the same in the days immediately preceding as during the experiment, it is assumed that the feces collected during the first two or three days of the investigation were not materially different in amount and composition from those collected in the latter part of the period. Any error introduced in this way could hardly be important.

Urine.— This was collected for each subject separately in twenty-four hour periods, beginning at 11 o'clock in the morning of June 19th. At this time, immediately preceding the morning row the bladder was always emptied.

It will thus be seen that the quantities of solid and liquid excreta were determined for each subject, but the food consumed was determined only for the four men taken together. It is hoped that at some future time it may be possible to determine both the food and the excretory products of individual persons. It was obviously necessary, in this case, to make the investigation of as little trouble as possible to the men, and on this account no attempt was made to determine the food consumption of the individuals separately.

Methods of Analysis. — The methods followed were, in the main, those adopted by the Association of Official Agricultural Chemists,[9] with such modifications as have been devised from time to time in this laboratory. The total nitrogen was in all cases determined by the Kjeldahl method, with the special manipulation suggested by one of us.[10] The fat was determined by extraction with ether and the mineral matter by incineration, with the usual precautions. The water was determined by drying in a water oven for a period of five hours. In vegetable food materials and in milk the difference between 100% and the sum of the percentages of water, protein,[11] fat (ether

[9] See U. S. Department of Agriculture, Division of Chemistry, Bulletin 46.

[10] Journal of American Chemical Society, 22 (1900), p. 259.

[11] It is a common custom to estimate protein, both of animal and vegetable foods, as N x 6.25, thus assuming an average of 16%

extract) and mineral matter (ash) was taken as indicating the proportion of carbohydrates; in other words, carbohydrates were estimated by difference.

The heats of combustion of food and excretory products were determined by means of the bomb calorimeter.[12] The combustion of solid materials, like bread, meat, etc., are made by compressing air-dry or partially-dried material in pellets, and burning them with a large excess of oxygen in the bomb. The accurate determinations of the heat of combustion of urine is, however, more difficult, owing to the tendency of urea to decompose into ammonium carbonate during the process of drying. We have followed the method suggested by Kellner,[13] which is in effect the saturation of a cellulose "absorption block" of known weight and known heat of combustion with a known amount of urine, drying in an oven at about 60° C. and burning in the bomb calorimeter. The heat of combustion of the urine taken is the difference between the total heat given off and that produced by the combustion of the cellulose block.[14]

In the analytical work involved in the investigation here reported, we are indebted to the valuable aid given by Dr. J. F. Snell and Messrs. P. B. Hawk, E. Osterberg and E. M. Swett. The determinations of urea and uric acid, however, were made by Dr. E. W. Brown, who has made a special study of the subject in the laboratory of physiological chemistry of Yale University. The urea was determined by the Mörner-Sjoguist[15] method and the uric acid by the Hopkins[16] method.

Sampling and analysis of food materials.— In order to make the statistics as exact as possible, practically all the food consumed was sampled and analyzed. In the case of uncooked foods this is not so imperative. The composition of ordinary raw food materials can be estimated approximately from the averages of a large number of analyses of different materials which have lately accumulated. The composition of cooked materials is, however, uncertain, both because only a few analyses have been made of cooked food and because the methods of preparation of the same materials or "made dishes" differ widely. The quantity of nutrients in a roast of beef depends not only upon the composition of the raw material, but also upon the amount of water and fat which are removed in roasting. The composition of mashed potatoes depends not only upon the composition of the potatoes themselves, but upon the amount of butter and milk, or cream, which may have been added. It was, however, impracticable in this investigation to analyze samples of every kind of cooked food. The following general plan for sampling and analysis was therefore adopted:

All food materials were sampled, with the exception of raw eggs, lady fingers, shredded wheat, bread pudding (which was served but once), sugar and fresh fruit. A composite sample of the meats was obtained by taking, as an aliquot subsample, one-tenth of the weight of each kind of meat served at each meal. These various aliquot subsamples were united in one large composite sample of all meats eaten. This composite

[1] Undetermined.

[2] Found to contain 5.97% alcohol by weight, and 3.8% other organic matter. Since the heat of combustion of alcohol is 7.1 and the heat of combustion of carbohydrates about 4.1 calories per gram, it follows that 1 gram of alcohol is isodynamic with 1.7 grams of carbohydrates (7.1 ÷ 4.1 = 1.7). The 5.97% of alcohol in the ale may therefore be assumed as equivalent to 10.1% of carbohydrates. Assuming the remaining 3.8% of organic matter to be sugars or starches, the total organic matter in the ale is equivalent to 13.9% of carbohydrates.

[3] Found to contain 6.7% alcohol by weight, isodynamic with 11.5% carbohydrates.

[4] Assumed to contain 14.5% alcohol by weight, isodynamic with 24.6% carbohydrates.

of nitrogen in protein of both animal and vegetable foods. The proportion of nitrogen in protein of vegetable food, especially of the cereal products, appears to be greater than 16%, and requires a smaller factor than 6.25. The factors for protein here used are stated in Table 8 beyond. For a full discussion of the proper nitrogen factor for computing protein, see discussion by Atwater and Bryant, Reports of Storrs' (Conn.) Agricultural Experiment Station, 1899, pp. 74–79.

[1] This is the 324th study of the series referred to in footnote 7.

sample was used for analysis. Similar composite samples were taken of all kinds of fish, of soups, of breakfast foods, etc.

Some of the sauces and desserts were not completely analyzed; since they did not form an important part of the diet, the amount of dry substance only was determined, and the composition of this dry substance was assumed from other analyses of the constituent food materials. The error thus involved can hardly be large enough to affect materially the results.

The percentage composition of the food materials used in the study is shown in Table 1. Those designated by laboratory numbers were analyzed; the composition of those designated by the letters *a* and *b* was estimated, as stated in a footnote to the table.

Collection and analysis of feces.—The feces were collected for each subject during the whole period of the experiment, and were analyzed separately; the figures thus show in each case the composition of the whole quantity for seven days. The percentages apply to fresh (not partly dried) substance. The results are shown in Table 2.

The amount and composition of the urine will be discussed later.

THE DIETARY STUDY.

The figures of Table 3 show the kinds and amounts of food eaten by the four men on each day and during the whole seven days of the experiment. For the reason explained above it was not found practicable to weigh the amounts eaten by each man separately. The food materials were weighed as they were put on the table ready for eating. The portions left uneaten were also weighed. The quantities here given are those actually eaten; they were found by deducting the amounts not eaten from those served.

TABLE 4.—NUTRIENTS AND ENERGY IN DAILY FOOD OF FOUR ATHLETES.

DIETARY STUDY NO. 324.

Food Eaten.	Total food. Grams.	Organic matter. Grams.	Nitrogen. Grams.	Protein. Grams.	Fat. Grams.	Carbohydrates. Grams.	Fuel value. Calories.	Heat of combustion. Calories.
June 19, per man	2,822	768	27.5	169	156	443	3,840	4,215
" 20, " "	3,205	831	29.9	183	177	471	4,195	4,601
" 21, " "	3,035	785	24.5	149	135	501	3,800	4,139
" 22, " "	3,143	805	25.3	155	168	482	4,040	4,417
" 23, " "	2,945	808	24.2	148	164	496	4,035	4,370
" 24, " "	2,129	707	19.6	118	149	440	3,560	3,849
" 25, " "	3,007	801	25.9	158	162	481	4,000	4,360
Total 1 man, 7 days.	20,286	5,505	176.9	1,080	1,111	3,314	27,470	29,951
Average per man per day for 7 days	2,898	786	25.3	154	159	473	3,925	4,279
Total 1 man for 6 days, excluding Sunday, June 24,	18,157	4,798	157.3	962	962	2,874	23,910	26,102
Average per man per day for 6 working days	3,026	800	26.2	160	160	479	3,985	4,350

The amounts of nutrients and energy in the food eaten are found by applying the figures for composition in Table 1 to those for quantity in Table 3. They are summarized in Table 4.

It thus appears that these four young men, who had been selected from several thousand university students because of their combination of muscular strength and endurance, and the higher qualities needed for success in a severe physical contest, and had been in vigorous training for several months, on a diet such as experience implies to be fitted to the purpose, ate food supplying, on the average, per man per day:

	Average for 7 Days.	Average for 6 Working Days.
Protein	154 grams.	160 grams.
Fats	159 "	160 "
Carbohydrates	474 "	479 "
Total energy	4,279 calories	4,350 "
Fuel value	3,925 "	3,985 "

It is to be noticed that the figures for the total energy of the nutrients express the total heat of combustion. The fuel value is found in the digestion experiments as stated beyond.

Comparison of results of this and other studies. — Table 5 compares the results of the dietary study just described with those of a number of other studies of similar character. The figures for Nos. 2 to 8 of the table represent the food eaten by the members of the Harvard and Yale University crews while in training, first at Cambridge and New Haven and afterwards at Gales Ferry, for the race of 1898. Nos. 9 and 10 are for the foot-ball teams at Wesleyan University and the University of California. No. 11 is the diet for a single day of Sandow, who is remarkable for his feats of muscular strength, as lifting. With the figures for the food eaten by these athletes are given the average results of a considerable number of studies of people at ordinary occupations: college students and families of mechanics, farmers and professional men in different parts of the United States. All of the dietaries in the table belong to the general inquiry above referred to.

The protein of the food of the four athletes of the Harvard crew of 1900 averages 154 grams and the fuel value 3,925 calories per day. The average for the Harvard and Yale University crews in 1898 was almost exactly the same; protein 155 grams, and fuel value 3,955 calories. So close an agreement is doubtless accidental, but it is interesting that the quantities of food eaten by these four men should be so close to the averages found in the previous studies. It is evident that the quantities of food eaten by these men did not differ materially from those eaten by the other college crew men in training. The college foot-ball teams had much more of both the protein and energy in their daily food. The food of Sandow contained somewhat more of energy and very much more protein.

The number of studies thus far made does not suffice for an accurate measure of the food consumption of people of different classes at ordinary occupations in various parts of the United States. It seems probable, however, that the figures in this table are not very far from the actual averages. The ordinary food of students at different colleges and universities, as shown by the figures in the table for 15 college clubs, gave 107 grams of protein and a fuel value of 3,580 calories. The corresponding average in families of mechanics, farmers and professional men, as calculated for adult male members, is not far from 100 of protein and 3,315 of energy.

TABLE 5.— COMPARISON OF QUANTITIES OF NUTRIENTS IN FOOD OF ATHLETES AND PEOPLE OF ORDINARY OCCUPATIONS.

(Nutrients in food actually eaten per man per day.)

No. 1. Described above.

Nos. 2-8. Reported by W. O. Atwater and A. P. Bryant, Bulletin 75 of the Office of Experiment Stations, U. S. Department of Agriculture, Dietary Studies of University Boat Crews. These are Nos. 227-233, respectively, in the series of dietary studies referred to in note 7.

No. 9. Reported by W. O. Atwater, Report of Storrs' Experiment Station, 1891, p. 128.

No. 10. Reported by M. E. Jaffa, in Bulletin 84 of the office of Experiment Stations, U. S. Department of Agriculture. Serial number of study 268.

No. 11. Reported by C. F. Langworthy and W. H. Beal, in Report of Storrs' Experiment Station, 1896, p. 158. Serial number of study, 179.

Nos. 12-16. Reported by W. O. Atwater and associates in various Bulletins of the Office of Experiment Stations, and Reports of the Storrs Experiment Stations. Summarized by A. P. Bryant in the Yearbook of the U. S. Department of Agriculture, 1898, p. 439.

That athletes eat considerably more than people in ordinary life is what would naturally be expected. An especially interesting feature of

the food of the athletes is the much larger amount of protein in proportion to the fuel value than is found in the food of people with ordinary muscular strain; that is to say, in increasing their food over the ordinary consumption, the athletes added much more proportionally to the protein than to the other nutrients (fats and carbohydrates). The large proportion of protein in the food of men subjected to intense muscular strain has been a matter of frequent observation in the United States and Europe. Why and to what extent it represents a physiological necessity is not yet fully known. It seems very natural, however, that where great muscular strength and effort are needed, there should be corresponding muscular development, and this would be most naturally attained by the use of nitrogenous food.

(To be continued.)

PUERPERAL INSANITY.[1]

BY EDWARD B. LANE, M.D., BOSTON.

WHEN your president asked me to speak tonight on the subject of puerperal insanity, I told him that I felt somewhat embarrassed, as I was asked to talk about something which I believed did not exist.

I do not wish to be understood to deny that insanity occurs in conjunction with the puerperal state, for, unfortunately, this distressing complication is frequently seen. Nor do I wish to deny that the puerperal condition is not an exciting cause, for I know that it is. I object to the term "puerperal insanity" to define a distinct type of mental trouble, as I do not find such in practice.

Many years ago I asked myself this question: What is there diagnostic of puerperal insanity about this patient? — one against whose name in the clinical record stood that diagnosis. Can the alienist in going through the wards of a hospital for the insane for the first time, without assistance, name the cases of puerperal insanity from objective symptoms? I do not believe he can. At any rate I cannot. We can diagnose objectively general paresis, mania, melancholia and katatonia; but we must receive the history of recent childbirth before we make a diagnosis of puerperal insanity. This term is one of many descended to us from the old etiological classification of the English and Scotch writers. This has been more elaborately subdivided into insanity of pregnancy, puerperal insanity, and lactational insanity. Again, we hear of puerperal mania and puerperal melancholia. Such a nomenclature not based on mental symptoms alone leads us to hopeless confusion, and is most unscientific.

But you did not ask me to go into the endless subject of nomenclature of mental diseases,— a branch of medical science of which none of us may feel proud. I will only ask you to remember that I do not recognize a distinct type of mental disease the immediate result of the puerperal condition, and the obstetrician need not, in looking for the origin of these distressing symptoms, confine himself to incidents of the labor or its sequelæ.

It is commonly said that heredity plays an important part in the causation of puerperal insanity. This may be true, but I seriously question if it is any more potent in these cases than in insanity in general. It is always an important contributing cause; but it certainly is not a cause for our giving a more grave prognosis than we would in a case where there was no insane heredity.

At the risk of exhausting your patience I will venture to ask you to follow me in a hasty statistical inquiry. I was much interested in consulting the statistical returns of this subject, and I then asked the pertinent question; if the puerperal condition is an important factor in causing insanity it can be numerically expressed, if we can learn what is the excess of insanity among pregnant women over the amount of insanity among women in general between the ages of twenty and fifty. Let us take the facts in our own city, so far as we can get at them from the statistics furnished.

You already know that insanity is a disease of middle life. Census returns tell us that 70% of all insanity develops between the ages of twenty and fifty. It is highest relatively among those between thirty and forty; that is, the chance of becoming insane is greater between the ages of thirty and forty than at any other period of life.

There are today in our city not far from 280,000 women; that is, female population. Of these nearly one-half, or 135,000, are between the ages of twenty and fifty. Out of the total female population of the city 1.26 per 1,000, or 353 women, will be committed in one year as insane. According to the figures for the United States, 70% of these will be between the ages of twenty and fifty. But in our city there is a very large proportion of old people committed, and the true proportion would be a little over 60%. Sixty per cent of 353 would be 212 cases. We have a right to expect, then, no less than 212 women at the child-bearing age will become insane. How many of the women of this age are likely to be confined during the year? The vital statistics tell us that 18,000 living children will be born in our city during the year. There are no available figures as to the number of still births or miscarriages which may be expected to occur. This would be essential to an accurate estimate, but I will ignore it for the present. All but an insignificant number of these births will occur among the women of the ages chosen for our figures. If, then, insanity overtakes the 18,000 mothers in the same ratio as it will certainly occur among all women at this age, we may expect 28 cases of insanity to occur during pregnancy or soon after confinement. If we add to this, let us say, 2,000 more cases of miscarriage or still-births, we should have 31 cases of puerperal insanity. But the figures for Massachusetts for one year and those for the Boston Insane Hospital for ten years, which are nearly alike, show that only a fraction

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, February 27, 1901.

over 4% of cases among women are puerperal. (It is an invariable custom to tabulate the cause as puerperal in the case of any woman who becomes insane during pregnancy or soon after. This, by the way, against the figures of 6% and 7% given in earlier times in England and this country.) And 4% of our total of 353 cases of insanity among all women in Boston is only 14. So that we arrive at the very interesting result that, as a matter of fact, insanity associated with childbirth occurs only one-half as often as it does among women in general at the child-bearing age. To use the terms of the insurance actuary, it would be a good risk to insure a pregnant woman against insanity, or, at least, against commitment for insanity.

I confess I am surprised at the result of this query, and am tempted to inquire further and seek as to why it is so. Among the insane the single outnumber the married; and it is possible that mental defect manifests itself so early that a large number who are to become insane never marry.

I believe it is demonstrated that the puerperal condition is not an important factor in the causation of insanity.

To illustrate the present scepticism on the subject of puerperal insanity, I will give briefly the experience with so-called "puerperal insanity" at the Boston Insane Hospital for the past year. In this time we received 202 women patients, of whom 6 (only 3%) were considered as puerperal cases. Here I use the word "puerperal" in its broadest sense, including all cases when the mental disease came on during pregnancy, or the lying-in period, or during lactation. As a fact, in only one of these six cases did the symptoms begin within ten days of childbirth.

CASE I. Mrs. W., twenty-three years. Became melancholy seven weeks after her baby was born. Thought she had done wrong. She seemed to improve, and her family considered her nearly well when she relapsed, and when the child was three and one-half months old she was committed. She was confused, frightened, said she had let her husband go, and wanted to kill herself. She doubted her husband's identity. There were hallucinations of hearing, and she tried to jump out of the window after her husband.

Since admission she has been very dull, and will seldom speak to any one in the hospital. She speaks more to her husband; is good-natured, but apathetic. Sits like a bashful child before the physicians. She gained remarkably in weight. She does not improve, and probably never will. A case of hebephrenia.

CASE II. Thirty-four years of age; married. One week before admission gave birth to a dead child. She states that she felt no life for a month, and it is believed that the child had been dead that time. She was confined by a midwife, and had no physician in attendance. For two weeks after admission her temperature ran from 100° to 102°. A gynecologist saw her in consultation, and the uterus was curetted and placental tissue and pus removed.

Her first mental symptoms were hallucinations, and she was suicidal. Later she was delirious, noisy and good-natured. This was followed by depression with dullness. She recovered what was probably her natural mental condition (which was never of the best) in six months, and went home. This was a delirious mania (probably septic), followed by depression.

CASE III. Has been insane five years, following a miscarriage, which was caused by slipping on the ice. Four years ago she gave birth to a living child. Soon after became much excited, probably as a result of delusions. Tried to kill her husband. Thought her food was poisoned. Hallucinations of sight and hearing. Refused to eat at one time. Has grown demented. On admission here was quiet and listless. Probably a case of hebephrenia, which had become demented.

CASE IV. Forty years of age. Husband left her many years ago, and she has been living with another man, by whom she had children. October 4th, while six or seven months pregnant (she does not know which), she was admitted to the hospital. She had been suffering from poverty, and probably not properly fed. For three weeks has been actively deluded; thought food was poisoned; was frightened. Later thought she might be dead, and was to be judged. Asked saints to forgive her; apparently felt something akin to remorse, for her illicit relations with her companion. She improved mentally in a week, and in three weeks seemed rational. She was discharged, sent to a State hospital, where she could be confined. This case is called puerperal because she chanced to be pregnant.

It is quite like other cases which come to us which are not complicated in this way, and I think her privation had more to do with it than the pregnancy. This was called a case of acute delusional insanity.

CASE V. Thirty-two years of age; married. This patient, like the previous one, became insane in the seventh month of pregnancy. For two months she suffered from hallucinations of hearing, which caused her to become insane in October. The voices told her she must leave the house, which she finally did one night, when only partially clad. She broke into another house.

On admission she was very quiet, but anxious about her children. She was depressed, but the depression was evidently secondary to her delusions. Could answer all questions intelligently, but refused to speak unless addressed. Had to be urged to eat. This condition continued for a month. She was then transferred to another hospital, that she might be confined. Diagnosis was made of acute delusional insanity.

CASE VI. Twenty-two years old; married. Has had three children,—two dead; youngest is living; was born October 1st. Seven weeks after confinement she began to be insane. Had laughing spells, and cried a good deal, also. She had not slept; said she had worried. She was excited at times; thought people were down on her.

Since admission she has been somewhat depressed; confused at times. She has had hysterical attacks; at other times suddenly excited. This is probably a case of hebephrenia.

This year's record gives, perhaps, a fair example of an experience with puerperal cases. Only one of the six was, in my opinion, a case of mania, and this was similar to the cases of puerperal mania of the older textbooks. These six cases fall, then, into no less than four types of mental disease. The only case of mania was that in which no physician had attended her during confinement, and placental tissue had been retained in the uterus.

Before leaving this subject I desire to read the history of three cases which are more like the cases we read of in the textbooks, and which occurred before the last year. I think they are instructive, and more nearly what we have been accustomed to regard as puerperal insanity.

CASE VII. Twenty-two years old; married. Admitted January 31st. Primipara. Child nine days old. Family history was unknown. She was a Catholic, and had been married about a year; was not married by a priest, and this had worried her at times. She was in excellent physical condition. The labor was not especially severe. She was cared for by a careful and excellent practitioner. When the child was four days old she became exhilarated; she laughed and sang. Then she paid no attention to the baby. An eminent specialist saw her in consultation, and gave it as his opinion that there was no sepsis. She grew more restless, and would not stay in bed; removed the dressings and clothing. She thought she saw the devil. Five days after mental symptoms developed she was committed to the Boston Insane Hospital.

On admission she was profane, obscene and vulgar; extremely restless, and would not stay in bed. Temperature 102.2°; pulse 116; respiring freely; took her nourishment well. The day after admission, mental condition the same; pulse 116, fairly strong and regular. Purulent stain noticed on napkin. Vaginal douche of corrosive sublimate given. Temperature 102° A.M., 104.2° P.M.

A small contusion with small slough noticed on posterior wall of vagina, one inch above perineum. Vagina packed with iodoform. It was thought this would explain the temperature, but soon an abundant purulent discharge appeared. Temperature 105° A.M. It was evident that there was trouble other than the vaginal ulcer to account for her condition. A gynecologist was sent for, and patient was highly stimulated. The surgeon curetted the uterus, and removed considerable purulent matter. But, although she stood the ether well, the temperature rose, and the pulse became weaker. She died on the evening of the fourth day.

This was a case of septic delirious mania. It is a question if there may not have been a double infection here, as the maniacal symptoms are said to have appeared before the sepsis was apparent.

CASE VIII. Admitted September 5th; aged twenty. Primipara. Baby seven days old. This woman was refined and used to comforts. During pregnancy her husband had been out of work, and she was deprived of some comforts. An additional cause of worry was potent, as an indiscreet relative had heated discussions on religious topics, urging her to change her belief, and tried to destroy her confidence in her husband. At the time of confinement there was little to do with, and besides the worry was added the mortification of her poverty. She had lost much sleep during pregnancy. When the baby was five days old she became excited; laughed, got out of bed, and gave imperious orders. She locked herself in her room. She made mistakes of identity; thought she could mesmerize people. Refused food and medicine. Was very emotional.

On admission to the hospital was restless and excited. For the first week her temperature varied from 99°–102°, and it became normal eleven days after admission; that is, eighteen days after confinement. The perineum had several stitches, which were removed in due time. It was necessary to use artificial feeding. There was much insomnia. Hypnotics were used for five weeks. Great excitement continued for seven weeks, when she became quieter and seemed apprehensive. She now began to eat well.

During the months of November and December she was talkative, silly, and frequently quite excited for a day; at other times quiet and timid; but her physical condition improved. During January the maniacal condition persisted. She was extremely mischievous, and used vile language. In February a decided improvement was noticed, and she exhibited more self-control; and in the middle of February she expressed a desire to go home to her husband. She said she could remember many incidents of her illness, but it was very confused. She could not believe she had been in the hospital six months. On February 26th she had gained very rapidly, and was discharged recovered.

This may be considered a typical case of acute mania. It is not one of the short cases of delirious mania of septicemia, but it was the usual course of acute mania. There was some temperature which I believe to be due to some toxic substance, quite possibly due to an infection, but more likely not the common septic poison.

The mental strain from worry, the loss of sleep, the exhaustion incident to confinement, co-operated to bring on the nervous symptoms. We must not forget that undoubtedly there exists a varying susceptibility to this toxic substance (whatever it may be), and those most susceptible possess an idiosyncrasy such that this poison causes in them maniacal symptoms. We must not be too ready to say a patient has a neurotic temperament.

CASE IX. Admitted November 19, 1898. A woman thirty-two years of age. Was admitted in a condition of acute mania. She had been incoherent in speech, very restless and excited for the past week. Began by being hysterical, noisy and irrational. Claimed she was not sick, and

could get up. Thought the milk given her was poison. Became very noisy, and was untidy; was tied in bed. Had hallucinations of sight and hearing.

On admission was very restless, and it was necessary to tie her in bed. Could be urged to take a good amount of liquid nourishment. Erratic in conversation. Trional and sulfonal administered to procure sleep. In ten days she cleared up mentally, with a relapse on the twelfth day, when she was confused and restless. She improved rapidly after this. In thirty-two days she went home, and was entirely recovered.

This case is a very good illustration of the mental disturbances seen in puerperal mania, and I cite it here because the cause was due to an ischiorectal abscess, and the excitement came on within thirty-six hours after an operation for the abscess. No sleep after the operation, and acute delirious mania followed. There was undoubtedly some toxic infection here, although not a septicemia. The patient had been suffering much pain for two weeks before the operation. She had become reduced physically, and was very hysterical before the operation. Loss of sleep and pain had produced a certain amount of exhaustion of the higher nerve centres. It is fair to assume that two pockets full of pus in the lower pelvis had given rise to some toxic substance, which had entered the circulation, and a brief delirious mania followed. This condition is probably not more a true insanity than acute alcoholism, and a recovery is to be expected as soon as the toxic substance can be eliminated and a few nights' sleep obtained.

THE HOME TREATMENT OF TUBERCULOSIS *VS.* THE CLIMATIC TREATMENT.[1]

BY EDWARD O. OTIS, M.D., BOSTON.

All treatment of pulmonary tuberculosis is in one sense climatic. Wherever you treat the disease certain climatic essentials are indispensable. These I consider to be: First and foremost, pure air; next, freedom from dust and high winds; a fair amount, at least, of sunshine; a reasonably dry soil, and freedom from sudden, great and frequent variations of temperature. There are other climatic and regional conditions desirable and beneficial, but not essential; namely, altitude, dryness of the atmosphere, equability of temperature, continuous clear weather, absence of excessive heat or cold. Some or all of these additional climatic conditions enhance, as we all recognize, the value of the climate, *per se;* but when they have to be obtained by compelling the patient to be acclimated twice over — first to the new climate and then again reacclimated to the old — it is a debatable question whether the additional gain is worth the price paid. There are also various other sacrifices which have to be made for the gain, which I will mention presently.

[1] Presented as a part of the discussion upon this subject at the American Climatological Association, May 31st, at Niagara Falls.

If, for example, the Colorado climate and that of Rutland, Sharon, Saranac or Lakewood, were equally accessible and equally easy of choice, I should say choose by all means Colorado, for it possesses a greater number of favorable climatic factors; but when we weigh the demands to be complied with in order to obtain the Colorado climate, by the resident of the East or North above those of the other near-at-home resorts, it is a question whether the additional climatic excellences are worth the additional cost.

Since we have arrived at a realizing sense of the fundamental principles involved in the hygienic-dietetic treatment of pulmonary tuberculosis, the importance of climate, though great as it is, is now held, and with truth, I believe, to be but one of the factors in the ensemble of the treatment. Formerly, as we know, climate was considered the predominating ray, the sole factor. At one time it was a warm climate like Florida, and the exodus of patients was in that direction. At another a cold climate like Minnesota. Then the altitudes, and the rush of patients was to Colorado. This magic of climate as the totality of treatment, as I have said, now no longer holds sway; but any region whose climate permits the patients to continuously, or as nearly that as possible, remain out of doors in pure air, is a favorable one for the hygienic-dietetic treatment. Viewed in this light the "home treatment," as here defined,[2] is qualified to accomplish favorable results, and those already obtained in Europe and this country attest the soundness of this proposition.

In the home climate, moreover, there is the indubitable advantage of retaining the patient in the same climate in which he has previously passed his existence, and where he must live — in a large majority of cases at least — the remainder of it. Whatever risk there is in a double radical change of climate is obviated. Even so enthusiastic a partisan of the Colorado climate as Solly writes: "It is fair to assume that about 50% of the total number coming to Colorado can return to their homes to live in safety; provided, of course, the danger to them in returning home is only climatic."

Furthermore, by treating the patient near his usual and accustomed residence, we take advantage of the psychic influence of familiar surroundings. A favorable mental attitude is no small factor in the cure of disease, as we all know. I recall the case of a patient whose improvement was more prompt and rapid from embracing the cult of "Christian Science," all through the hopeful mental attitude it placed him in, and the freedom from fear it produced. Proximity to friends and familiar scenes, if not abused, buoys up the spirits and strengthens the will; nothing is more depressing than nostalgia.

Again, the pecuniary factor is a very important consideration with a large number of patients. The expense of a long journey and residence in a

[2] It is understood that the term "home treatment" will be considered to mean the treatment in home climates; that is, in a hygienically suitable locality as near as possible to the patient's usual residence.

distant health resort, even if by dint of sacrifice and exertion it can be attained, is a source of more or less constant worry. "Here I am," says the patient, "spending all this money, and after all shall I recover?" "If I do not recover within such a time I shall be obliged to return, because my money will be exhausted." How often have our Colorado confrères reiterated the statement that the most essential requisite in coming to this resort is a well-lined pocketbook.

With the exception of Brehmer's and Dettweiler's experience and that of a few others in sanatoria, it was not until a comparatively recent date that even phthisiotherapeutists assured themselves or realized that pulmonary tuberculosis could be successfully treated in a home climate like that of England, Germany or New England. The favorable experience of the last decade in these countries has been a revelation, I think, to us all, and an attestation of the truth that no excellence of climate will compensate for the disregard of a carefully arranged plan of life, adapted to the individual patient, constantly insisted upon with authority, and supervised by the expert phthisiotherapeutist. If the strenuous life leads to moral victory and achievement, it none the less leads to success in the struggle against tuberculosis. Comparing sanatorium treatment at home with non-sanatorium treatment in a health resort, I doubt whether the additional climatic excellence compensates for the absence of the sanatorium régime. Try as he will, and be as faithful as he may, I do not believe it possible for the physician in a free resort to exercise that despotic power and personal influence over his patients which the physician in a closed resort is enabled to do. In the one case absolute power is possessed; in the other it is not. In either case a firm will and a sympathetic nature is essential on the side of the physician; but in the one case these attributes have full play, and in the other they do not.

It does not seem to me that we are yet in possession of sufficiently accurate and extended statistics of treatment, under the two different conditions here discussed, to judge, with any great precision, from the results obtained. The conditions as to stages of the disease, class of patients, detail of treatment, etc., vary so greatly that comparison of results seems both impossible and unfair. For example, at Rutland, out of an almost unlimited number of applicants, only the very incipient and most hopeful cases are selected; and to compare results obtained under these ideal conditions with those of other sanatoria or free resorts, where cases of varying stages and differing degrees of prospective favorable issue are received, would be manifestly unjust and misleading.

Then, again, before we are in a position to determine the end results, several years must elapse. Further, it seems to me that we must compare sanatorium results with sanatorium results, and open-resort results with open-resort results.

The statistics which have been used to show the advantages of the high altitude treatment over the home and sanatorium treatment, like the large number collected by Solly, and given in Hare's "System of Practical Therapeutics" and elsewhere, are those, it must be remembered, of ten years or more ago, before we thoroughly appreciated and employed, as we do today, the hygienic treatment of tuberculosis in all its strenuousness. The results we are obtaining today would, I believe, give a more favorable showing for the home treatment. Knoff[3] is the authority for the statement that cures effected in our home climates have been more lasting and more assured than cures obtained in more genial climates away from home. In this opinion concur Leyden, Gerhardt, Dettweiler, Walthers and others.

If other things were equal, which, as I have pointed out, they are not, I am inclined to believe that a sanatorium favorably located in the Rockies, Alps or other altitudes, conducted on the same lines as Dettweiler's at Falkenstein, would, with the same class and stage of cases, produce better results than a sanatorium in our home climates. Turban's elaborate report of results at Davos, published in 1900, appears to show this.

In conclusion, it must be a source of great congratulation to us all who are engaged in the treatment of tuberculosis, that the prospects of success in the home treatment appear so auspicious. It is the very small minority of the tuberculous who are able or willing to travel far afield for a resort in which to take the cure. The majority, for one reason or another, must, if the hygienic cure is attempted at all, undertake it near home.

Clinical Department.

A CASE OF MARKED CYANOSIS, DIFFICULT TO EXPLAIN.

BY SYLVESTER F. MCKEEN, M.D., BOSTON.

IN *The Boston Medical and Surgical Journal* of December 7, 1899, and of March 15, 1900, Dr. Richard C. Cabot reported two cases of "chronic cyanosis without discoverable cause." The following case presents quite a striking resemblance to these, and would seem to be of sufficient interest to warrant publication:

Henry H., a German, age fifty-three, packer in an iron foundry, came to the Medical Out-patient Department of the Boston City Hospital on May 6, 1901.

Family history.— Excellent.

Previous history.— About twenty years ago the patient had an attack of dyspnea for the first time, which laid him up for eight days. This came on suddenly, and was accompanied by no other symptoms, such as cyanosis, edema, palpitation, etc. Similar attacks have recurred at intervals of six months to two years. No other previous illness. Not subject to coughs. Denies venereal disease. Drinks one glass of whiskey, four glasses of

[3] Prophylaxis and Treatment of Pulmonary Tuberculosis, 1899.

beer, and two cups of coffee on an average daily. Smokes and chews fifteen cents' worth of tobacco per week.

Present illness.— He first noticed blueness of the face and hands about one year and a half ago. It came on suddenly, while at home recovering from one of his attacks of dyspnea above referred to, and has persisted with frequent exacerbations ever since. The cyanosis often increases suddenly, and his face and hands become "as blue as blueing," without any accompanying dyspnea or other symptoms of distress. He keeps right on with his heavy work, in spite of the marked cyanosis. Exertion does not seem to increase it particularly, nor cause any dyspnea. Increased blueness is seldom associated with dyspnea, although when he has one of his attacks of shortness of breath he is always more cyanotic than usual. About every two or three days he has attacks of blurring of the vision, followed by sweating and vertigo, when everything in the room seems to go round, and he is obliged to seize hold of some support to prevent his falling. Is not troubled with headaches, or noises in the ears. When very blue his hands feel cold and numb. For the past two years about, he has been subject to frequent attacks of diarrhea, sometimes causing prolapsus recti. Once there was blood in the stool. Appetite good. Sleeps well, but has to get up once every night to urinate.

Physical examination.— Well developed, but rather thin. Mind active. No dyspnea. Respiration 18. Extreme cyanosis of face, especially of the lips, tib of nose, and ears; small veins and capillaries of skin dilated. Hands and feet also very blue; most marked in a dependent position, less so when upright or horizontal. Circulation very slow in skin of other parts of body. An erythematous rash on shoulders and front of chest. Slight clubbing of fingers. Slight pitting over tibiæ.

Eyes.— Conjunctivæ injected; pupils equal and react; fundi show retinal veins engorged and filled with very dark blood, but are otherwise normal.

Mouth.— Tongue deeply cyanotic; gums swollen and bleed easily; many teeth loose and decayed; mucous membrane of cheeks and pharynx purplish.

Larynx.— Negative, except for congested appearance; no obstruction.

Pulse.— Rate 65; occasionally a little irregular, tension not high; walls of arteries slightly thickened and roughened.

Heart.— Area normal to percussion; area of flatness marked; apex beat in fifth intercostal space within the nipple line; action for the most part regular; no murmurs; aortic second not accentuated.

Lungs.— Somewhat hyperresonant over upper front; no dulness beneath sternum; no râles.

Liver.— Upper border of dullness begins at seventh rib in mammillary line, and extends two fingers' breadth below costal margin; edge not palpable.

Spleen.— Upper border of dullness at eighth intercostal space in midaxillary line; edge plainly felt an inch below rib margin, descending to two and a half inches on deep inspiration.

Abdomen.— Negative; tache cérébral absent.

Reflexes normal; sensation normal; a few small glands in post-cervical and inguinal regions. Temperature 98.1°.

A careful examination with the fluoroscope by Dr. F. H. Williams showed only emphysema, with consequent enlargement of the right heart, diminished excursion of the diaphragm, and depression of the liver; no mediastinal tumor or aneurism made out.

Urine.— Twenty-four-hour amount 70 ounces, normal color, acid reaction, specific gravity 1.015, trace of albumin, sugar absent; total urea, 35 grammes. Sediment contained a few granular casts, renal cells, leucocytes and abnormal blood corpuscles.

Blood.— Counts from the ear, finger and toe gave 9,440,000, 9,840,000 and 9,380,000 reds respectively; whites, 9,000, of which the polynuclears formed 74%, small mononuclears 18%, large mononuclears 6%, and eosinophiles 2%. Hemoglobin 120% plus.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY F. B. LUND, M.D., BOSTON.

(Concluded from No. 24, p. 585.)

ON THE FAVORABLE INFLUENCE OF PREGNANCY UPON ENTEROPTOSIS.

Maillart[8] has for several years interested himself in observing the effect of pregnancy upon the large class of patients with entero- and gastroptosis at the Canton hospital in Geneva, and has come to the conclusion that patients emaciated and debilitated by this disease recover a remarkable degree of health on becoming pregnant. Far from completing the destruction of an already shattered constitution, he found that pregnancy arrested the disease, and often produced a complete disappearance of the symptoms.

The conclusions at which he arrives are, in his own words, the following:

(1) In cases of enteroptosis the advent of pregnancy increases the intra-abdominal pressure as soon as the uterus has attained a certain size.

(2) Under these circumstances pregnancy produces an improvement in the digestive and general nervous system, which reveals itself by an increase of from 2½ to 6 kilograms in the body weight between the time of impregnation and the close of the puerperal period.

(3) As a result of judicious treatment this improvement, which often approaches in character a complete recovery, may be made more or less permanent, so that in the months which follow the pregnancy a further increase in weight may result.

[8] Centrbl. f. Gynak., No. 50.

(4) In the cases in which other causes, such as renal disease, the neglect of proper treatment, etc., prevent this improvement from taking place, pregnancy produces in general no actual ill effects upon patients with enteroptosis,—surely not in the cases which suffer from constitutional neurasthenia. The measures taken to favor the permanence of the temporary improvement which takes place during pregnancy must be begun during the pregnancy, and continued during and after the lying-in period. All the cases which Maillart treated were provided with a suitable abdominal support before pregnancy, which was continued during the first four months, and then replaced by others of sizes suited to the gradual enlargement of the abdomen. The clothing was also so arranged as to depend entirely from the shoulders, and produce no pressure upon the waist or hips. After the child is born a Glenard bandage is applied at once over the ordinary bandage, in order to maintain the intra-abdominal pressure, and enable the patient to turn freely in bed without the falling of the entire abdominal wall and contents to one side. The period of rest in bed is made as long as possible, and should be naturally longer in cases of enteroptosis than in ordinary cases. After leaving the bed the same support is worn as before the pregnancy. Under these measures the abdomen almost completely recovers its former firmness and size, and the organs are maintained in their former positions and under suitable pressure. The proper training of the child as to regular times of feeding,—waking not more than once in the night, etc., is even more important for the good recovery of the mother in these cases than in others; and the nursing and care of the baby have a favorable influence upon the mother by directing her attention from the selfish consideration of her own symptoms to the care and upbringing of her baby.

LACTATION ATROPHY OF THE UTERUS.

L. Fraenkel[4] concludes as follows from a study of 95 cases which have been investigated in an extremely thorough and careful manner.

The controversy between authorities as to whether lactative atrophy of the uterus is a physiological or pathological phenomenon; whether the prognosis is favorable or unfavorable, and whether it is advisable to stop the nursing and resort to artificial feeding, may be answered as follows: Lactation atrophy of the uterus is generally a physiological process. It occurs in the vast majority of nursing women, but not in all. It corresponds closely to the universal physiological atrophy of the uterus, which occurs when the degeneration of the muscle fibres after parturition makes faster progress than the regeneration. This appears to occur most often in cases of malnutrition, and is also a normal condition in lactation. Lactation atrophy begins generally during or before the third month of nursing, and is recovered from as a rule spontaneously either after weaning or during the nursing period; very frequently it has disappeared by the seventh month of nursing, even in cases where the baby has not been weaned.

Recovery is so frequent that women who have nursed their babies for nine months or longer, and come to the physician with complaint of amenorrhea, are oftener found to be suffering from another pregnancy than a lactation atrophy; and when the complaints are of gynecological symptoms other than amenorrhea, a uterus of normal size or larger is found more frequently than an atrophied uterus. In case of persistent symptoms attributed to a lactation atrophy, between the third and seventh months of the nursing period, the baby should not be weaned, except in special cases where the symptoms are very severe or the general condition of the patient makes it advisable. (A slight or moderate anemia does not indicate weaning.) An examination of the uterus should be made every four weeks, with a view to determining whether it is increasing in size, remaining stationary or growing smaller. Under the latter conditions nursing should be stopped; under the second, stopped after the seventh month, and under the first, allowed to continue for a year.

In the cases in which the uterus continues to grow smaller, or does not increase after the seventh month of lactation, there is reason to fear that the pathological type of lactation atrophy may ensue. This is commonly a result of nursing for too long a period, though it occurs in only a small fraction of the number of women who nurse their babies too long. This "atrophy through superlactation" has a doubtful prognosis, even under prompt and efficient treatment, and frequently proves incurable. For these reasons a too long nursing period is to be avoided in all cases.

REPAIR OF LACERATED CERVIX, CURETTEMENT, AND RAPID DILATATION OF THE CERVIX.

Deaver[5] protests against the indiscriminate use and abuse of these three operations, which although in themselves excellent procedures and capable of accomplishing much good and the relief of suffering, are often the cause of harm, because performed without due deliberation and knowledge of the conditions and contraindications. Certain of the remarks and comments of the writer are so sensible as to be worthy of repetition and careful consideration on the part of the large number of practitioners who operate upon these cases.

A lacerated cervix, says the writer, in women who have borne children, is so common that it may be considered more of a normal than a pathological condition. In the absence of special indications such a cervix had better be let alone, for to operate under these circumstances subjects the patient to useless risks without a commensurate reward. If, however, there is eversion with exposure of mucous membrane to injury, or if ulceration be present, or an excessive amount of scar tissue,—and these conditions produce subinvolution or marked reflex symptoms,—then opera-

[4] Archiv. f. Gynak., 1900, xxvi, p. 121.

[5] Philadelphia Medical Journal, March 2, 1901.

tion is indicated. Any hereditary tendency to carcinoma would indicate operation in such a case.

As strong as are these indications for operative intervention, the writer does not regard it as justified unless there is freedom from all pelvic inflammatory processes and their results. Salpingitis, pyosalpinx, or adhesions, offer strong contraindications. Under these conditions abdominal section for the correction of the intra-abdominal trouble should follow immediately the repair of the lacerated cervix.

In the presence of endometritis great care must be exercised to prepare the endometrium, if this be possible, prior to the narrowing of the cervical canal; or, in other words, to decrease the discharge so that the new and narrow canal will carry it off. These operations, unless carefully and aseptically performed, as every surgeon of experience can testify, are capable of converting a latent salpingitis into an active one. This may be due to the introduction of sepsis through intrauterine douching or instruments, or the spread of sepsis through an infected uterine cavity, or the breaking up of periuterine adhesions, liberating septic foci which have been walled off. Washing out the uterus, except in septic conditions, also plugging the cavity with iodoform gauze, Deaver regards as vicious practices, and capable of exciting salpingitis. Even in septic conditions the washing should be carefully done and the packing introduced for the purpose of drainage, and not to its exclusion. Curettement of the uterine canal is a dangerous operation, and one which calls for great delicacy of touch and the most rigid observation of aseptic and antiseptic details. The writer then alludes to the indications for the operation as septic conditions of the cavity, both acute and chronic, and characterizes the so-called curative effect of the operation *per se* as nonsense, and one which should be relegated to the Christian Scientist. If the surgeon by logical reasoning cannot arrive at the conclusion to operate in a given case, he had better let it alone; an operation should be attempted only to remove an existing pathological condition, and not one which is simply supposed to exist, or which might exist.

The reliability of the information derived from an examination of specimens curetted from a uterine canal in which malignant changes are expected is doubtful. It is very difficult to make a positive diagnosis ofttimes between chronic benign lesions of the mucous membrane and early malignant changes; and the small and fragmentary nature of the specimens interferes with a satisfactory examination.

Dilatation of the cervix is an operation too frequently performed, and without a proper appreciation on the part of operators of its indications and dangers. The dilatation by tents or by gauze and sponge packing offers no advantages over divulsion, and is attended by much greater risks of sepsis. Divulsion should never be performed except under complete anesthesia and under the most rigid asepsis. Dilatation is indicated in dysmenorrhea due to cervical stenosis, as a preliminary step to curettement when there is a displacement of the uterus which is not adherent, and when there is an absence of tubal inflammation, either active or latent. Dilatation as an attempt to correct flexions of the uterus must be classed among the surgical failures, and in the condition of an infantile uterus accompanied by dysmenorrhea the operation will be merely an ineffectual attempt to restore a congenitally defective organ.

The necessity for careful asepsis and delicate manipulation in these operations would indicate that their performance should be confined to the realm of surgery, and not classed as work which is the duty and prerogative of the general practitioner of medicine.

CYST FORMATION IN OVARIAN TISSUE LEFT AFTER OVARIOTOMY.

Ehrenfest[6] writes as follows: It is as yet undecided whether the practice of leaving a portion of the ovary in certain gynecological operations is an advantage or a disadvantage to the patient. The opinions of the best authorities are directly opposed to each other, and many additional statistics will be required to settle the question. The observations of Fischer[7] and Waldstein[8] have an interesting bearing on this question. Cases of cyst formation in portions of ovaries left behind at operation, either intentionally or unintentionally, are reported. Such examples are not very common; perhaps about as common as the development of carcinoma in the stump of a cervix left after supravaginal amputation, but nevertheless commoner than is generally believed.

Martin[9] says: It seems to me a question worth serious consideration whether ovaries in which small cystomata have developed and which lie with the diseased tube in a diseased peritoneum ought not to be removed, together with the tubes. Martin is inclined to think that they ought to be removed, as he has had to operate a second time in six instances for the removal of ovarian tissue left at the first operation.

In American literature the following instances of cyst formation in ovaries left behind at operation have been recorded: H. C. Coe[10] reports a case in which the left tube and ovary and the right tube without the ovary were removed per vaginam on account of a gonorrheal infection. Pain continued after the operation. Later a tumor the size of an orange was found to have developed to the right of the uterus. In May, 1897, a cyst of the right ovary, which was only slightly adherent, was removed by a median laparotomy.

At a meeting of the New York Obstetrical Society in February, 1900, Coe again reported such a case. In 1897 the left tube and ovary were

removed by a laparotomy. In March, 1899, owing to acute symptoms the right tube, which was thickened and obstructed, was also removed, but the ovary, which appeared to be normal, was left behind. In February, 1900, a third laparotomy had to be done for the removal of a cyst of the right ovary, the size of an orange, which had caused severe symptoms. In the discussion Waldo reported that he had recently observed a similar case, and McE. Emmet reported 2 such cases.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

W. H. GRANT, M.D., SECRETARY.

REGULAR meeting February 27, 1901, DR. E. S. BOLAND in the chair.

DR. EDWARD B. LANE read a paper entitled

PUERPERAL INSANITY.[1]

DR. ARTHUR C. JELLY: I should agree with Dr. Lane in general, and especially in what he said from the specialist's point of view, about being unable to regard puerperal insanity as an entity. For the obstetrician, however, there are certain advantages to be gained by considering together these cases of mental disorder which he meets in practice now and then under conditions more or less closely associated with the puerperal state, and where this appears to be at least an exciting cause. Because, if the attending physician knows that certain women are likely to develop insanity at such times, he has an additional reason for guarding against exhaustion and for meeting symptoms of nervous irritability when they first appear. It is true that sepsis is bad enough, but insanity due to sepsis is worse. Though less frequent than formerly, undoubted cases of this sort have not entirely ceased to appear. Moreover, it is not impossible that an existing sepsis may sometimes have been overlooked in certain cases where we have inferred that death was due to simple exhaustion, because the temperature was not very high. In the *Lancet*, 1898, No. II, page 83, a death was reported from puerperal septicemia where the temperature was subnormal throughout, though tested by two thermometers.

As Dr. Lane has said, it seems probable that there are toxic influences as yet not at all understood which lead to forms of mental disorder during puerperal states. This is another reason for careful attention to the eliminative functions.

When called to see these cases at home, one is usually asked, "Is this merely a temporary mental disturbance that will not get very severe, or is it an attack of real insanity?" Because, while any sacrifice is not too much for the family to make for a few days, if the attack is likely to last long, or to be very severe, the patient must usually be sent to an hospital for insane. In these cases, symptoms due to alcohol may simulate insanity so closely as to make a diagnosis very difficult. Women who are ordinarily abstinent frequently take liquor at the menstrual period, during pregnancy, after a miscarriage or confinement, or take ale regularly while nursing a child. Thus it frequently happens that a woman whose nervous system is unstable, who is neurotic, or neurasthenic, or epileptic, or slightly weak-minded, presents symptoms due partly to alcoholic and partly to other conditions. The picture thus presented may be very different from ordinary delirium tremens. In fact, there may be no more tremor of tongue and hands than seems consistent with the state of mental excitement; and the excitement may seem naturally to follow from the delusions of the patient. The common hallucinations of sight associated with crawling things may be absent, while other visions may or may not be present; and hallucinations of hearing are quite as common as those of sight.

I have seen several cases of this sort. If the patient can be deprived of alcohol, it will usually be possible in a few days to decide whether the attack is due largely or wholly to alcohol. Such are likely to be of short duration, though they sometimes last several weeks. Moreover, such patients are frequently so excitable that it is difficult to keep them at home even for a few days. Epileptics during confinement or shortly afterward are especially liable to have convulsions, or attacks of violent excitement, which appear to come instead of convulsions.

I have the history of one case of hystero-epilepsy who was formerly under Charcot's care, whose first child was stillborn after a long labor and the use of forceps. Two convulsions quickly followed delivery, and within two days an attack of violent excitement, which lasted less than a month.

In somewhat the same way a woman who has never controlled her emotions or passions will sometimes become excited and violent at such times, and present such a clinical picture that only close observation for several days will enable the physician to decide whether she is insane or not.

Such a case I saw recently. A multipara, in poor physical condition, had a miscarraige, followed by profuse hemorrhage, for which she was packed by a competent physician. She passed a sleepless night. The next day she refused the doctor's services, and would not talk to anybody. The following day, after another night without sleep, she refused food of all sorts, lay on her face in bed, would not speak. When the physician pointed out to her the danger of neglect, and urged treatment, she kicked him away from the bedside. Later in the day she declined to have anything to do with another physician. At 5 P.M., however, she talked with me in a calm and rational manner, took liquids promptly, but showed at times a tendency to be flighty and silly. She promised to allow the removal of the packing. The next morning she kept her promise, and agreed to go to the City Hospital

[1] See page 606 of the Journal.

for further treatment. When the ambulance arrived she declined to stir, but was calm. Soon afterward, however, she became excited, talked loudly, threatened her husband in most violent language, and appeared to be utterly beyond reason or control. I found the husband taking care of the two children on the sidewalk. He said it was not safe for them to go in, for she had repeatedly bruised him and torn his clothing in former attacks of temper.

The following morning she was civil to everybody, and submitted to treatment. She has shown no mental symptoms since.

This woman presented on one day a very good picture of resistive depression tending to stupor, due to exhaustion, and on the next symptoms of marked excitement. Either, if persistent, would have warranted a certificate of insanity.

I have related this case in detail because it seems to me to illustrate so well the possibility of grave error unless the physician uses great care and insists upon such deliberation and delay as to render it certain that the disturbance is more than transitory. In the prognosis of the mental changes seen sometimes early and more frequently late in pregnancy, one should be somewhat guarded; for, though the symptoms are usually mild and transitory, two cases about which I knew something died apparently from exhaustion, and several have developed chronic insanity.

Moreover, after miscarriages severe forms of mental disorder may arise.

DR. SARAH E. PALMER: I have had very little experience with puerperal insanity. I recall one case I saw at the New England Hospital. A woman was brought in in labor. She had been ill-treated and underfed, and had puerperal insanity, we thought, as a result of acute anemia.

DR. BOLAND: I feel that the section is under obligation to these gentlemen for the pains they have taken in presenting this subject. The subject has not been presented in the section for a number of years at least. As I remember my insane-hospital experience twenty odd years ago, we used to get an occasional case of that kind coming in shortly after delivery, and we were generally hopeful of recovery, as of any acute case. I was a little surprised, when I left the hospital fifteen years ago, that I did not see more cases of puerperal mania. I think in fifteen years I have only seen one case I could class as such. In this case there was a temperature which, according to the old test, would put this case out of the category. The case made a good recovery. The general practitioner I think sees the class of cases Dr. Thompson referred to — the cases of transient mental disturbance accompanying pregnancy — very apt to blossom out at delivery, and a little different type apt to come from the exhaustion of lactation. These cases usually occur among the poorer classes who have to struggle to make both ends meet, often have thoughtless husbands and a family of children to look after. The condition is one of anemia, exhaustion, etc., readily relieved by intelligent treatment at home, if they have the means.

AMERICAN SURGICAL ASSOCIATION.

ABSTRACT OF PAPERS AND DISCUSSIONS AT THE TWENTY-SECOND ANNUAL MEETING, HELD IN BALTIMORE, MD., MAY 7, 8 AND 9, 1901, THE PRESIDENT, DR. ROSWELL PARK, OF BUFFALO, N. Y., IN THE CHAIR.

(Concluded from No. 24, p. 593.)

DR. ROBSON read a paper entitled

THE SURGICAL TREATMENT OF CHRONIC ULCER OF THE STOMACH,

and stated that the treatment of these cases is at first essentially medical. He compared the treatment of ulcer of the stomach with that of ulcer of the leg, and particularly referred to the tendency to relapses. Twenty-three affections were referred to as complications of the condition, which were looked upon as serious menaces to the treatment of the ulcer. He believes that about 25% of cases of gastric ulcer treated medically died, while only about 16% treated surgically died, according to statistics a year ago; but at the present time, while the percentage death rate in cases treated medically remains about the same, it has been reduced to 5% under surgical treatment. A number of operations were mentioned from which one could take his choice, and great stress was laid upon the importance of the proper preparation of the patient before operation. Each operation was described in some detail, and cases illustrating each form of operation, together with the results obtained, were quoted. The number of operations performed by the author, divided up according to the number performed of each kind, were given, and the method he employs in stomach and other operations, involving the making of an anastomotic opening between the hollow viscera, was described. The author demonstrated the method, which consisted practically of the employment of a method of suturing over a decalcified bone bobbin. The advantages claimed for the method are: (1) That it secures the opening, being of the exact size intended, and that there is no possibility of the passage being made too small by the drawing up of the sutures before the knots are tightened; (2) that it secures an immediately patent channel between the two anastomosed viscera; (3) that the bobbin protects for from twenty-four to forty-eight hours the new line of union from pressure and from the irritation of the visceral contents; (4) that it facilitates the application of the sutures, and so adds to the expedition of union by sutures; (5) that no foreign material is left in the alimentary canal which may irritate or cause subsequent trouble, for the bobbin rapidly dissolves in the alimentary juices; (6) that the method has now been proved by ample experience to be rapid, easy, efficient and safe.

The discussion on the foregoing paper was opened by DR. WILLIAM J. MAYO, of Rochester, Minn., who considered at some length the treatment of open ulcer of the stomach by gastro-enterostomy, which he considered the most generally indicated operation for this condition,

in view of the following reasons: (1) The varying extent and reasonable probability that more than one ulcer exists; (2) the common location of the ulceration; and (3) the impossibility of locating the exact site of the ulcer in many cases.

In some few cases presenting special features he believed that excision or other form of surgical procedure is indicated. The symptoms, he stated, depend somewhat upon the situation of the ulcer, the most common location being near the pylorus, which position may introduce certain mechanical features, and in the relief of these secondary phenomena, in his opinion, the operation achieves its triumphs. The relief of hyperacidity and a prompt emptying of the ingesta, preventing irritation and aiding nutrition, are secured by gastro-enterostomy.

Reference was made to the fact that the earlier reports on this subject demonstrate the existence at that time of a belief that the stomach was always contracted, but later reports have proven the error of considering this a fixed condition, although it is no doubt true in a majority of cases. In acute ulcer the stomach is usually small, and if the ulcer is not in the vicinity of the outlet it will probably remain so. On the contrary, it is during the healing process that many ulcers in the pyloric region become most troublesome. Ulcers in this situation are often extensive, and in chronic cases, perhaps, but partly cicatrized, and obstruction of the pyloric orifice may take place by distortion or narrowing of the opening, irregular symptoms of the unhealed portion of the ulcer being manifest, in addition to the dilatation. In these cases periods of health alternate with symptoms of open ulcer, which are later followed by signs of open ulcer in a stomach more or less dilated. Most of the cases when once cicatrized remain healed, although a few sometimes develop into open ulcer. While the capacity of the stomach is not usually materially altered in cases of gastric ulcer, when this condition does exist it has a surgical significance.

He then made a comparison of the results of gastro-enterostomy in (1) ulcers in the pyloric region with a normal or enlarged stomach, and (2) ulcers in a contracted stomach, and stated that, in cases coming under the first group, gastro-enterostomy is the operation of choice, as it delivers the ingesta at a point sufficiently remote from the disease to prevent irritation, and the healing process is not interfered with and develops rapidly; immediate and satisfactory relief for the mechanical condition is obtained, and in five gastro-enterostomies performed under his observation all were speedily and permanently cured.

Reference was made to a pyloric spasm produced by a small ulcer at the pylorus, by which symptoms resembling mechanical interference are produced. While the author considers that pyloroplasty is fairly effective in this form of the disease, he states that it does not compare with the benefits derived from gastro-enterostomy, although the division of the pyloric sphincter terminates the spasms, and the enlargement of the opening exerts a healing influence on the ulcer. Gastro-enterostomy on the small stomach, affected by ulcer, does not as a rule give immediate relief, although the ulcer will eventually heal; but the results are not so good as in the other class of cases. The author then referred to the use of the Murphy button, and the union of the jejunum to the anterior wall of the stomach as near the greater curvature as possible, which operation he considers equally as good as the posterior, and easier of performance. He stated that three-fourths of the cases which had come under his observation had been operated on for the relief of non-malignant disease, largely pyloric obstruction, the result of healed ulcer; and that there had been but one death in over 40 cases. In malignant cases the death rate was over 25%.

DR. W. G. MACDONALD, of Albany, reported two cases of gastro-enterostomy for the relief of chronic ulcer of the stomach. One case, which had existed for eight years, did very well for ten months, when distinct symptoms presented themselves of a well-developed tumor in the region of the pylorus, the patient dying shortly afterward of carcinoma of the stomach. The second case was very similar, except that the improvement following the operation lasted for a somewhat longer time. In his opinion the ideal operation for these conditions is extirpation of the ulcerated surface, even though it involves resection of the stomach or partial gastrectomy.

DR. WILLIAM L. RODMAN, of Philadelphia, called attention to the fact that malignant degeneration frequently takes place on the site of an old benign ulcer, and also that the great majority of gastric ulcers are situated posteriorly and not anteriorly. In his opinion adhesion plays a very important part in these conditions; but he felt that if the ulcer is anterior and free from adhesions the operation should be done, while if it is posterior it is out of the question.

DR. ROBSON did not close the discussion, except to thank the gentlemen present for the interest they had taken in his paper.

DR. R. MATAS, of New Orleans, read a paper on

ARTIFICIAL RESPIRATION,

and demonstrated a new apparatus therefor.

THIRD DAY.— MORNING SESSION.

DR. R. MATAS, of New Orleans, read a paper on

THE TREATMENT OF THE ARTERIOVENOUS ANEURISMS OF THE SUBCLAVIAN VESSELS,

and reported a case of bullet injury occurring in a man aged twenty-four years, in whom the right subclavian artery and vein had been perforated through the scalenus auticus. The bullet had also injured the brachial plexus, causing paralysis of the corresponding upper extremity. The operation was performed ten days after the injury. An osteoplastic resection of the clavicle with disarticulation at the sternoclavicular joint was made under local infiltration anesthesia with

Eucain B., and a temporary traction loop of silk was applied under the first portion of an anomalous subclavian artery, the innominate being absent. The vein was provisionally compressed above and below the anastomotic orifice. Notwithstanding complete control of the subclavian at its origin, profuse hemorrhage took place from the anastomotic orifice when the vein was detached from the artery, the bleeding stopping when double ligatures were applied above and below the perforation in the artery. The bleeding indirectly came from the vertebral and internal mammary. After dividing the artery between the ligatures, the orifice in the vein was closed by lateral suture, and the venous circulation was reestablished. A bullet, undeformed, 38 calibre, was extracted. Shock followed, but patient was restored by saline infusion. Recovery with partial loss of hand and forearm from mortification, caused by arterial ischemia and insufficient collateral circulation. Primary healing of operative wound. In reviewing literature of the subject the author referred to 15 cases of this rare injury which had been recorded since 1829, when Larrey described the first case. Of these, only 4 had been operated upon. The indications for intervention, the prognosis and details of the operative technic closed the paper.

This paper was discussed by Dr. Arthur Dean Bevan, of Chicago, Dr. W. S. Halsted, of Baltimore, Dr. Theodore A. McGraw, of Detroit, and closed by Dr. Matas.

Dr. E. H. Bradford, of Boston, read by title a paper on

SUBTROCHANTERIC OSTEOTOMY.

Dr. Albert Vanderveer, of Albany, N. Y., read abstract of paper on

PHLEBITIS FOLLOWING ABDOMINAL OPERATIONS.

The great field of abdominal surgery has been so carefully and thoroughly investigated, and the operative technique perfected to such an extent, that we go on doing operations with, perhaps, as little strain and anxiety as used to present to the operating surgeon in much less serious surgical work; yet, occasionally, some unlooked-for complication will arise. My abdominal work gives me more anxiety during an epidemic of grippe. Acute perforative appendicitis is more prevalent in August and September, because of the diet in which young people indulge. Also in December and January, because of exercise and exposure. Only lately have I had that disquieting symptom of phlebitis—four cases in the past two years. In operations deep in the pelvis, ligating the uterine and ovarian vessels and applying a mass ligature, it is fortunate we do not have more serious complications than is generally met with. Where these do arise suspicion may occur at once as to some failure in technique; but we should consider the great range of pathological lesions met with in the pelvis. It is very unpleasant, but very necessary in these cases, to keep the patient two or three times as long as promised at first.

In the following cases it is well to be remembered that they came somewhat near each other, and immediately after moving into and beginning our work in a splendid new hospital plant. Our other operations of every kind were doing well, and every usual precaution had been exercised.

Case I. Mr. H. N. S., age fifty-eight; a very rare case. Angioma in connection with the lobelus spigelii; removed by Dr. Macdonald and myself. Two weeks later patient developed marked symptoms of phlebitis in the left leg. Under treatment the edema and swelling ultimately disappeared, but it was over three months before the patient regained entire use of his leg.

Case II. Mrs. A. F. C., age forty; double ovarian tumor removed. On the twelfth day after the operation, phlebitis of the left leg appeared. Under treatment the patient made a good recovery in three weeks.

Case III. Mrs. J. N., age forty-four. Patient gave a long history of disease. An operation was performed and a large fibroid was removed. Patient did well until two weeks later, when a distinct phlebitis of the left leg appeared. Under treatment the patient recovered, and was discharged from the hospital four weeks later.

Case IV. Mr. W. H. B., age twenty-nine; strong and healthy. Gave a history of four or five attacks of catarrhal appendicitis. The usual operation was performed and appendix removed, seven inches long, with concretions in distal extremity. Patient developed phlebitis of the left leg on the fifth day. Treatment usual, and a good recovery resulted. There was never any evidence of pelvic complication.

The literature on this subject is very scarce, and there is great question as to whether phlebitis in these cases is of septic origin. In my own cases I am not altogether sure but that the tight bandage may have had something to do with at least two of them. Never has there been delay in the union of the wound.

Pain was one of the pronounced symptoms. When the lesion presented there was also a varying and accelerated temperature and pulse. Sex makes no apparent difference, neither does the nature of the operation. In all four cases the patient was in a horizontal position, so there was no extra pressure upon the vessels of the extremities. The pelvis was not elevated. Loss of blood slight. Patients all strong previous to the operation, with the exception of Case I. Ligatures used were silk; no catgut in the peritoneal cavity.

Phlebitis may be due to the anatomical distribution of the veins on the left side, as in varicocele. This may have some bearing on the pathology.

Constipation must always be overcome. Ether was used as the anesthetic. Urine carefully kept track of.

I quote reference to Dr. Strauch's paper on his experiences with ether narcosis, coupled with the high pelvis position, from which he draws the deduction that these two reasons combine to cause phlebitis, and especially of the left lower extremity in all cases.

The above paper of Dr. Strauch was reported in 1894, and since that time very few cases have been reported to the profession.

Treatment certainly consists in rest, elevation of the limb, free movement of the bowels, anodynes to control pain; later, hypnotics to afford sleep, diffusible stimulants and tonics as may be required.

DR. WILLIAM J. MAYO, A.M., M.D., of Rochester, Minn., read a paper entitled

AN OPERATION FOR THE RADICAL CURE OF UMBILICAL HERNIA,

stating that patients suffering from umbilical hernia are usually obese, with attenuated muscles. It is sometimes wise to reduce the weight before operation. The neck of the protrusion should be exposed early and its omental contents ligated off at this point, saving time. The writer has made the following method nineteen times. The steps of the operation are as follows: A traverse elliptical incision is made at the base of the hernial protrusion to and through the peritoneum. Traction upon the hernia exposes its contents at the point of entrance. Return of intestine, if present, and ligation of extruded omentum. Exposure of the aponeurosis above and below the margin of the incision. The lower flat of aponeurosis and peritoneum is slid upward three-quarters of an inch into a pocket previously formed, between the upper margins of aponeurosis and the peritoneum. Retention by two rows of buried sutures. The sliding can be made from side to side in the same manner as was so performed in ten of the nineteen reported cases. If the ring is very large the overlapping from above downward is easier of performance.

DR. A. J. OCHSNER, of Chicago, considers that there are four methods of treatment of umbilical hernia in the adult which are worthy of consideration, and he briefly describes each one. A few cases he referred to in some detail as illustrating the various methods, and the speaker felt sure that any surgeon who had once tried Dr. Mayo's method was convinced of its value. After the operation has been completed the vomiting or straining does not seem to make any impression upon the repaired portion of the abdominal wall. In his opinion the method had so much to recommend it that it is not surprising it should have been invented independently by at least three different surgeons, of which Dr. Mayo was undoubtedly the first by several years.

DR. JAMES E. MOORE, of Minneapolis, Minn., presented a paper on

PREVENTION AND CURE OF POST-OPERATIVE HERNIA.

Ventral hernia is rare among good operators, except after operations for acute appendicitis. The causes of ventral hernia are sepsis, improper closure of the wound and drainage. The location of the wound is of less importance than its proper closure.

When rational principles are adhered to the exact manner of carrying them out may be governed by the operator's personal experience. Each tissue should be united to its own kind by through-and-through stitches of silk-worm gut and buried sutures of absorbable material. Buried sutures of unabsorbable material are objectionable and unnecessary. The crossed suture of Dr. Fowler is a very good one, but requires more time to apply, and causes more pain when removed than the through-and-through suture. Always avoid drainage when possible. Most cases of pelvic surgery requiring drainage are best drained through the vagina. The same rules should govern the treatment of post-operative hernia that govern the treatment of other herniæ. Operation is the only treatment to be considered, and it should be done early.

The prognosis after operation is good. In operating we should restore the parts to their normal relations, and hold them there until nature has united them. The peritoneal cavity should always be opened. Scar tissue should all be dissected away, and the various layers of the abdominal wall isolated, after which the wound should be closed by through-and-through sutures of silkworm gut and buried animal sutures. It is very important to bring the muscular tissue together. Simple cutting out of the scar and approximating the freshened edges will lead to disappointment.

This paper was discussed by DR. ARTHUR D. BEVAN, of Chicago, and closed by DR. MOORE.

AFTERNOON SESSION.

DR. S. H. WEEKS, of Portland, read a paper on

FRACTURES AND DISLOCATIONS OF THE SPINE,

which was discussed by DRS. JOHN C. MUNRO and S. J. MIXTER, of Boston, and DR. R. H. HARTE, of Philadelphia. The author did not close.

DR. CHARLES A. POWERS, of Denver, presented with photographs a paper on

GIANT SACROCOCCYGEAL TUMORS.

The subject of especial observation was a male child first seen at three months of age, at which time there was found an enormous growth occupying the sacrococcygeal region, extending laterally to the buttocks and forward in front of the anus. It was irregularly ball-shaped, and in size as large as the head of a child of six years. Below and in front the growth was cystic; above and laterally it was firm, and in places nodular. The skin over the tumor was of a bluish-red over the cystic parts, normal above and at the sides. Deep palpation showed no gap in the bony structures. There was nothing abnormal about the rectum. The tumor was moved by the gluteal muscles, but the tension of the mass was not changed when the child cried. There was no paralysis nor anesthesia of the lower extremities. No operation was advised, and the growth underwent spontaneous contraction. The skin did not

ulcerate, the contents of the cystic portion were absorbed, and when the child was three years and nine months old the tumor had shrunk to the size of a boy's fist and was well flattened out over the sacrococcygeal region. The boy is as strong and healthy as other lads of his age, lies on his back and sits like other children; except for its mere presence the tumor gives no symptoms.

While this growth lacks pathological confirmation, it is assumed that it is a teratoma or embryoid tumor having a double germinal substratum. A certain number of such tumors have been observed by German and French writers, and when pathologically examined have been found to contain the greatest diversity of tissue: cysts lined with various forms of epithelium, intestinal remnants, masses of gliomatous tissue, smooth and striped muscle fibre, bone, cartilage, etc.

The question of operation must be decided by the surgeon in the individual case. In general it is recommended that operation be deferred until the child reaches such an age as to enable it to successfully withstand operative procedure. The author's case shows that spontaneous contraction may occur.

THE RADICAL CURE OF INGUINAL AND FEMORAL HERNIA,

with a report of 800 cases operated upon from 1891 to 1901, was the subject of a paper by DR. W. B. COLEY, of New York, which was discussed by DR. J. COLLINS WARREN, of Boston, and DR. W. S. HALSTED, of Baltimore, DR. COLEY closing.

THE USE OF SILVER WIRE AND ELECTRICITY IN THE TREATMENT OF ANEURISMS,

with report of cases, was the title of a paper read by DR. LEONARD FREEMAN, of Denver. Discussion was participated in by DR. J. M. T. FINNEY, of Baltimore, DR. DEFORREST WILLARD, of Philadelphia, and DR. R. MATAS, of New Orleans, DR. FREEMAN closing.

DR. W. W. KEEN, of Philadelphia, read a paper entitled

RESECTION OF THE CHEST WALL FOR A LARGE SARCOMA; SUCCESSFUL USE OF THE ANTI-STREPTOCOCCIC SERUM.

The author referred very fully to the details of the operation, together with the condition of the patient before and after. In concluding his remarks he called particular attention to: (1) The method of separating the tumor from the chest wall so as to determine more exactly the limits of the disease and lessen the size of the opening to be made in the chest. (2) The division of the ribs anteriorly and posteriorly prior to opening the pleural cavity; this diminished very much the period of danger in the collapse of the lung. (3) The use of Fell's apparatus, which was not satisfactory in this case, and for which he prefers to substitute the apparatus of Dr. Bloom, of New Orleans, which he then showed to the association, or the apparatus of Matas, which was then demonstrated by its inventor. (4) The suture of the lung to the chest wall, which was followed by no untoward surgical result. It diminished very greatly the amount of post-operative pneumothorax, and in fact one might almost say abolished it. (5) The use of the antistreptococcic serum, and as to whether it was the cause of the fall in temperature or only a coincident, the results seeming to be so striking. (6) The examination of the blood, which was of great value as showing the reason for the continued high temperature, and led to what the author believes to have been the proper treatment for the condition.

In the opinion of the speaker it is too early to determine what will be the future of the patient; but up to the present time, a period of nearly seven months, the results have been entirely satisfactory.

DR. M. L. HARRIS, of Chicago, read a paper on

MOVABLE KIDNEY; ITS CURE AND TREATMENT.

which was not discussed.

The following papers were read by DR. S. J. MIXTER, of Boston: (1) Two cases of abdominal contusion: (*a*) "Fracture of Spleen-Splenectomy, with Recovery"; (*b*) "Fracture of Kidney-Nephrectomy, with Recovery"; (2) "Nephrolithotomy on both Kidneys"; (3) "New Method of closing the Defect following the thorough Removal of the Breast."

These papers were discussed by DR. J. COLLINS WARREN, of Boston, DR. J. M. T. FINNEY, of Baltimore, and DR. W. H. CARMALT, of Boston, but DR. MIXTER did not close.

DR. MATAS exhibited an apparatus which he used for local infiltration anesthesia. It consisted of a metallic (sterilizable) cylinder provided with an accessory gauge which indicated the level of the fluid within. The cylinder (capacity eight ounces) was filled with a weak Eucain B. solution ($\frac{1}{2}$, $\frac{1}{10}$ and $\frac{1}{100}$ of 1%) and was charged with a small air pump, which forced the fluid into the tissues by simple pneumatic pressure. After charging the cylinder the pump is detached, and the cylinder is connected to the needle and tubing by which the fluid is injected into the tissues. The advantages of this apparatus are, that it facilitates the introduction of large quantities of anesthetic fluid (Eucain B. dissolved in .8 salt solution) and completely edematizes the field of the operation by a process of almost continuous infiltration and without the interruptions caused by the frequent transfer of the ordinary syringes. It is especially advantageous when massive infiltrations over large areas are indicated with extremely weak solution, which anesthetize the tissues by their physical action alone rather than by the chemical analgesic action of the drug.

He had used the appliance all of the past winter, and had been much pleased with the results obtained in a great variety of operations, many of which without its aid would have been entirely beyond the scope of purely local anesthesia. It is also the most satisfactory apparatus that he has used for extensive hypodermoclysis in shock,

hemorrhages and other conditions in which it is desirable to inject rapidly a large quantity of physiological salt solution under the skin.

DRS. HEARN and ROE read a paper on

PNEUMOTOMY OF THE LUNG,

and exhibited a case of a large abscess of the lung of twenty-two years duration, probably the result of local gangrene following pneumonia. Patient male; age twenty-six.

Pneumotomy was performed, and the abscess drained for two years, with much improvement in general health; marked lessening of the previous horribly offensive odor, but without any healing or reduction in the size of the cavity.

They again operated and excised a portion of the abscess wall, stitching the margins of the remainder to the skin surface, thus converting it into an open cavity, with relief from the annoyance of wearing a drainage tube and of cleansing the cavity, and with practically entire cessation of odor.

Although about six months have elapsed the cavity remains unchanged, and there is evidence of secondary bronchiectasis, for which they assign two probable causes; that is, cough and cirrhosis of lung tissue. To obliterate the original cavity, and to relieve the bronchiectasis, or cure it, they propose to remove the greater portion of the lower ribs with their periosteum, in this way allowing the chest wall to collapse upon the lung.

The case demonstrates the great difficulty of definitely localizing an old abscess of the lung with tough, elastic walls which collapse when empty, by either of the two methods; namely, aspiration and palpation; the value of the x-ray; the practicability of giving ether as a general anesthetic; the absence of any embarrassment of respiration by the entrance of air through drainage tubes introduced into the cavity, although they freely communicate with the bronchus; the ease with which the cavity could be flooded with different fluids or solutions, although they entered the bronchus and caused expulsive paroxysms of coughing; the advantages gained by draining the cavity by tubes or by the open method, but without any evident obliteration of the abscess cavity.

A portion of the ninth rib in this case was resected the third time, having been twice reformed.

The presence of pleural adhesions rendered the operations in this case free from the dangers of pneumothorax, and although a localized pyothorax occurred subsequent to one of the operations, it did not delay convalescence.

DR. DEFOREST WILLARD, of Philadelphia, was chosen president of the association for the ensuing year.

The next annual meeting will be held at Albany, N. Y., in May, 1902.

AT the third annual commencement of Cornell University Medical College recently held, twenty-four candidates received the degree of M.D., a number of them being women.

Recent Literature.

Municipal Sanitation in the United States. By CHARLES V. CHAPIN, M.D., Superintendent of Health of the City of Providence. Pp. 970. Providence, R. I.: Snow & Farnham. 1901.

THIS extremely useful work is the result of a vast amount of research and of labor on the part of a practical sanitary administrator, in bringing together in one volume the different methods in actual practice in the cities of the United States. Disputed points are constantly arising in the work of health administrators, and oftentimes days and months are expended by local officials in searching the laws and regulations of states and cities for information in regard to methods of procedure, and for the precedents which may have been established by other boards of health. To all such officials this volume will prove extremely welcome. It is in no sense a work of theory, and, as the author states, "is not a treatise on the principles of sanitation, and in fact these principles are rarely referred to; but it is, rather, a compendium of sanitary practice."

If every local health official on entering upon his duties would make a thorough study of this volume, and then apply the knowledge thus attained to his daily routine, a great amount of labor, time and expense would be saved. The brief section entitled "Advancement of Knowledge" contains most valuable advice condensed in a few paragraphs.

While the work is not one of theory, the author's opinions are occasionally presented in a clear and axiomatic manner, and as the result of years of experience. For example, in treating of communicable diseases, he says: "There are few boards of health which do not have some of the commoner forms of communicable diseases constantly present; so that this problem of how to deal with communicable diseases actually existent occupies a large part of the attention of sanitary authorities, and is the important problem with which they have to deal."

Of the control of plumbing, he says: "While it would be more logical to vest this function in another department,—that of the inspection of buildings,—the earlier practice has been adhered to, and at present the control of plumbing is in most cities in the hands of the health department. This custom is doubtless due both to precedent and to the popular notion of the very intimate connection between poor plumbing and disease."

With reference to the importance of the registration of vital statistics, he says: "The registration of vital statistics is the firm basis on which the whole structure of sanitary science and practice must rest."

In treating of the sweat-shop system, he says: "The duty of the State to help the helpless, and make life more bearable for the most wretched of mankind, is reason enough for any action which will abolish or mitigate the sweat shop, without

conjuring up an exaggerated danger of sickness to the well-to-do." This accords with actual experience in Massachusetts, where, during the first four years of inspection under the provisions of the sweat-shop law, only one actual case of infectious disease was reported as existing in a family where such clothing was being made.

The topics treated are, in their order: Sanitary organization, registration of vital statistics, nuisances, specific nuisances, plumbing, water, ice and sewers, food other than dairy products, dairy products, communicable diseases (four chapters), refuse disposal and miscellaneous sanitary work. An appendix contains very many circulars and blank forms in use by local health authorities, and will prove very useful for reference.

The topics of communicable diseases and refuse disposal have been considered carefully and thoroughly, and are fully illustrated with plans and photographs of buildings and appliances in actual use, special attention being given to the subject of isolation hospitals for infectious diseases.

With reference to the general form of sanitary administration in the United States, it is stated that "local sanitary administration is provided for by law over the entire area of 36 states, including a population of 52,304,922 in 1890, or 83% of the total population at the census of that year. Twenty of these states have provided for a county form of sanitary government, and 16 states have a township form of sanitary government."

Saunders' Question Compends. Essentials of the Diseases of Children. By WILLIAM M. POWELL, M.D. Third edition. Thoroughly revised by ALFRED HAND, JR., M.D., Dispensary Physician and Pathologist to the Children's Hospital (Phila.). Pp. 259. Philadelphia and London: W. B. Saunders & Co. 1901.

This little book is open to the same criticism as all works of its class. We feel that they are almost certain to do harm to the student, as they do not give a clear picture of disease. It is impossible to do this in the form of questions and answers and in so short a space. This book is, however, far better than most of its kind.

The subject-matter is, as a rule, accurate as far as it goes. In many instances, however, the answers are more or less erroneous and very often state only half-truths. The student who uses this book entirely can hardly fail to get imperfect conceptions of many conditions and one-sided conceptions of all. He will do far better to spend his time reading one of the larger textbooks.

Hygiene and Public Health. By LOUIS PARKES, M.D., D.P.H., and HENRY KENWOOD, M.B., D.P.H. Pp. 732. Illustrated. London: H. K. Lewis; Philadelphia: P. Blakiston's Son & Co. 1901.

This sixth edition has been revised, and such changes and modifications have been made as were demanded by the rapid progress in hygiene. It has been written by practical administrators in charge of sanitary work in the populous districts of London, and is especially designed, as the authors state, "for those members of the medical profession who are studying for the various health diplomas." It constitutes, however, a valuable work of reference for the profession generally, and, with the exception of the last chapter, upon sanitary law, is well adapted to the use of the American student and medical man.

Details of laboratory work are not presented, since the authors very properly concluded that these subjects could be best presented in special treatises.

The fact that this work has reached its sixth edition speaks well in its favor.

The subjects presented are the following: Water; the collection, removal and disposal of excreta and other refuse; air and ventilation; warming and lighting; soils and building sites; climate and meteorology; exercise and clothing; food, beverages and condiments; communicable diseases and their prevention; disinfection; statistics and sanitary law.

The Theory and Practice of Military Hygiene. By EDWARD L. MUNSON, A.M., M.D., U. S. Army. Pp. 971, with 8 plates and 400 engravings. New York: Wm. Wood & Co. 1901.

Hitherto most of the different subjects relating to military hygiene have been discussed in small volumes and monographs relating to a few topics only, such as Tripler's manual for the examination of recruits, and others of similar character. But Dr. Munson has brought together in this comprehensive volume all that is essential to the military surgeon from the standpoint of preventive medicine.

The duties of the army medical officer, whether in peace or in war, demand a thorough knowledge of medicine and surgery and the treatment of disease; but he should also be trained in the principles of hygiene.

The volume is not only an admirable textbook for the medical student having army service in prospect, but is also the best work of reference on military hygiene yet published in English.

The general character of the book may be inferred from the following list of subjects which are treated: The selection of the recruit; the development of the recruit; the march in campaign; water supply; the ration; clothing and equipment; camp sites and camps; sanitary administration of camps, posts, barracks and hospitals; ventilation, heating and lighting; disposal of excreta; sewage and refuse; personal cleanliness of the soldier; military mentality and morbidity; diseases of the soldier; disinfection; habits of the soldier as affecting his efficiency; hygiene of hot and cold climates; the troop ship; disposal of the dead, and sanitary inspections. The two important topics, the ration and the diseases of the soldier, are very fully and thoroughly presented. In his treatment of the vexed subject of the army canteen, the author expresses a decided conviction in its favor. Upon this point he presents an array of facts in support

of his position, and says: "It is evident that, coincident with the general establishment of the canteen system throughout the army, there has occurred a decrease amounting to considerably more than one-half the drunkenness which formerly tended to the impairment of discipline, the demoralization of individuals, and to the occurrence of assaults, injuries and deaths. It is idle to deny that this result has not been largely due to the attraction furnished by the canteen, combined with the military discipline which prevails in that institution, and which reduces to a minimum the possibility of dangerous excesses."

The Economic Disposal of Town Refuse. By W. FRANCIS GOODRICH, A.I.M.E. Pp. 340, with 75 illustrations. London: P. S. King & Son; New York: John Wiley & Sons. 1901.

The disposal of refuse[1] has been more fully considered in England than in any other country, and has there reached its highest type of perfection. The valuable information contained in this volume, as presented by an English engineer, will be sure of a welcome by the sanitary officials of all our cities and large towns, many of which are still disposing of offensive refuse in primitive and objectionable modes.

The method most commonly in use in England is that of destruction by fire; and the object of the author is to describe the different destructors now in use, not only in England, but in all parts of the world.

The author has collected information from almost every known source, not excepting Rangoon, Shanghai and the *Boston Herald.*

A special chapter is devoted to the subject of the use of refuse for the purpose of converting it into power, or, in other words, using it as a fuel. Upon this point the author says: "In these days the refuse destructor is boldly associated with electric lighting of towns, sewage pumping, water pumping and other useful power purposes. Why? There is only one answer, and that is, because it is now generally recognized that refuse is a valuable asset, and possesses calorific value."

American experience in the disposal of garbage is treated in a separate chapter, with an introduction by Colonel Morse, of New York City, the noted expert upon this subject. His opinion appears to be clearly in favor of destruction by fire, as opposed to reduction and consequent extraction of certain products for commercial purposes.

[1] Garbage, offal and the waste of cities and towns.

LEPROSY IN FRANCE.—According to the *Medical Record* Dr. Besnier recently presented a report to the Paris Academy of Medicine regarding the increase of leprosy in France. The report stated that the disease was becoming so prevalent in various parts of the country that stringent measures were urgently needed for its suppression. In Savoy and Brittany there were several distinct endemic centres, and at the Hospital St. Louis, in Paris, fourteen lepers were at present under treatment.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 20, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE MASSACHUSETTS MEDICAL SOCIETY DINNER.

As indicated in our editorial notice of last week, each succeeding anniversary of the Massachusetts Medical Society shows signs of change and of improvement in the conduct of the meeting. Within the last few years the conviction on the part of the management has grown that the members come rather for conviviality than for a satiety of medical communications. The social side of the meetings has therefore become more and more prominent, and the literary part reduced in volume and scope. The custom now prevailing of having a few vital medical topics thoroughly discussed by a group of carefully selected speakers is altogether to be commended, as contrasted with the former method of indiscriminate paper reading on widely dissimilar subjects. This year the general subjects under discussion were, "Diseases of the nutrition of infants" and "The surgical aspects of diseases of the alimentary tract." A somewhat more general section, more particularly concerned with the results of laboratory investigation, completed the literary exercises, with the exception of the usual Shattuck lecture, by Dr. W. F. Whitney, on "The alleged increase of cancer in Massachusetts," a valuable statistical study, and the annual discourse, by Dr. George E. Francis, of Worcester, on "Forecast of the problems of medicine in the coming century."

A part of the proceedings, however, to which the members look forward with particular interest, is the annual dinner, which this year was peculiarly successful, both on its material and intellectual side. Wisdom was shown in the choice of after-dinner speakers, and also in the limitation of their number. President Eliot, of Harvard University, introduced by Dr. Draper as a friend of medical education, spoke feelingly

and forcibly of the growth of medical knowledge, and the self-sacrificing devotion of physicians in their investigation of the problems of disease. He said in part, that it was a source of congratulation that at these annual dinners singing was coming to be substituted for speeches; that a chorus of purely medical men typified the perfect harmony which existed throughout the society. He further spoke of the new education in the Harvard Medical School, which had become a laboratory of experimentation, and insisted upon the importance now, as always, of experimental study. He alluded to the far-reaching beneficence of the recent work on the etiology of yellow fever, as typifying the heroic side of the medical profession, and made a personal allusion to the late Jesse William Lazear, who sacrificed his life in the attempt to demonstrate the means of contagion of the disease. "This devotion to duty is due to no courage of the crowd, no gregarious enthusiasm like that of the battlefield; there are no witnesses, no shouts to encourage; it is the deliberate taking of a great risk. Is it not infinitely superior to the heroism of fighting? Yet it has all come out of the horrors of war; out of this has come the beneficent heroism of peace. There are none braver, none nobler, none more self-sacrificing."

President Capen of Tufts College spoke from the standpoint of a minister as well as of an educator. He acknowledged his embarrassment in facing an audience of medical men, and described his feelings on being called upon to speak as not unlike that of the deacon who when asked to lead a meeting in prayer, hesitated, and finally when asked whether he could pray, answered, "Yes, I can, but I hate to." He went on to speak of the change which had come about in medical education during the past few years, and of the subordinate place formerly given to the physical sciences, and especially to biology, which had now, in his opinion, become one of the humanities. He bewailed the attempt recently made in this State to tie the hands of medical investigators by restrictive legislation, and commented on the services physicians were rendering by appearing at legislative hearings against the legalization of quackery and humbug. He alluded in conclusion to the growth of the medical school of Tufts College, in which he felt a deep personal interest.

Mr. S. J. Elder, for the law, spoke both jocosely and seriously. Usually, he said, we have one of your number in a box, closed on three sides, but now you have one of us, enclosed on four sides. Of expert testimony he spoke as follows: I dislike many classes of experts; they have brought down upon themselves the criticism of the courts and the distrust of the community. At times such experts are practically paid counsel, but that is not true of your profession. After an increasing number of years at the bar, it is a satisfaction to say that the opinions of doctors are discriminating, fair and nonpartisan.

These various statements are good to hear from men outside the profession of medicine. No doubt they are somewhat exaggerated, to fit the occasion, but it is not likely that the average doctor will have his head turned by listening to such laudation once a year. It is certainly a gratification, amidst the storm of abuse in which the medical expert usually lives, to hear from the lips of so distinguished a member of the bar as Mr. Elder, that the expert is, after all, not so bad as some of the speaker's less distinguished colleagues would paint him.

Dr. Cheever closed the formal speaking by an appeal for the liberal support of the Boston Medical Library, as follows:

"As president of the Boston Medical Library I feel that I have a strong claim to your attention. All of my hearers may not realize the many years of effort which have at last given birth to our new library building. It is worthy of any society, and is a beautiful, chaste and appropriate edifice. Surely this marks a long step in advance for the profession in Massachusetts. A large library, containing files and fresh numbers of over 500 medical periodicals always at hand, besides 29,000 volumes of permanent works, will tempt the inquirer and reward the student. We have happily commemorated Dr. Oliver Wendell Holmes, Dr. John Ware, Dr. Fifield, in the halls named for them.

"The doctors of Boston, both of themselves and by soliciting others, have paid in $73,690. We have a mortgage debt of $50,000. Our great need now is for endowments, small or large, to buy new books. Any one subject in medicine could be pursued farther for an endowment of only $1,000, whose annual interest would purchase enough new books on that one subject each year. Let me urge you, gentlemen, to show your interest by becoming associate members, for $5.00 a year. Go and become familiar with the beauty of Holmes Hall, its many portraits, medallions and mementoes; visit the library; use the library; support the library."

PHYSICIANS AND THE LAW.

The legal relation of physicians to their patients is always a matter of some delicacy, and one which, unfortunately, not infrequently demands a final decision from the courts. It is altogether proper that a person who employs a physician should have a reasonable assurance of his faith-

fulness and skill, and it is incumbent on the physician to justify this assurance. The limit of a physician's duty to his patient is, however, an exceedingly difficult matter to determine. There is a strong feeling on the part of the laity that a physician's services are absolutely at the beck and call of the public; that if called to a case he has no choice but to go, and if in attendance on a patient is equally bound to continue his services until convalescence is established or death results. It is clearly a matter of very great importance that both the physician and the patient should be protected, and the interests of both safe-guarded by the law, which must always be the final arbiter in matters of dispute.

A case of considerable interest in this connection is reported as having recently occurred in California, establishing a precedent of no little importance to the practicing physician. The facts are said to have been essentially these: A physician, about whose capacity there seems to have been no question, was called to attend a young married woman. After duly considering the conditions he concluded that an operation of some sort was demanded; but when the time came for its performance the patient rather hysterically refused to have it done, whereupon the physician, who had previously told the patient that he would relinquish the case if she refused to act according to his judgment, left the house. An hour passed before another physician arrived, who thought it unnecessary to operate.

The first physician was sued by the aggrieved husband and wife, and a verdict was returned against him to the amount of $2,000. The case was tried before the Supreme Court of California, which stated that the defendant had shown himself neither unskillful nor negligent up to the time of leaving the case, nor did it hold that he had endangered the life or health of either mother or child. The Court, however, went on to define the duty of the physician under such circumstances, as follows: "It is undoubtedly the law that a physician may elect whether or not he will give his services to a case; but having accepted his employment and entered upon the discharge of his duties, he is bound to devote to the patient his best skill and attention, and to abandon the case only under one of two conditions: First, where the contract is terminated by the employer, which termination may be made immediately. Second, where it is terminated by the physician, which can only be done after due notice and an ample opportunity afforded to secure the presence of other medical attendance. . . . He can never be justified in abandoning the case as did this defendant, and the circumstances show a negligence in its character well-nigh to brutality."

So far as the statement at hand goes, there is no evidence to show that the physician left the case from any other motive than that his judgment was no longer respected by his patient; it furthermore would appear that he had given due notice of his intentions, and that his final action could therefore have been no surprise. In spite of these facts, the decision of the Court was strongly against the defendant. We have no adequate knowledge of this particular case, but we confess to a feeling of uneasiness when we contemplate the hold which such a decision gives to possible designing persons upon self-respecting doctors. A physician's position at once becomes ridiculous when his advice is refused; and yet, according to this decision, it appears that he must still continue his services, even after he has given what to the lay mind would seem to be a sufficient warning of his attitude. It is remarkable that physicians escape as often as they do from the toils of the law, under any circumstances, and it is certainly well that they should be prepared to meet all contingencies.

MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION.

THIS week the American Neurological Association is meeting in Boston, a choice which we may be pardoned for regarding as a wise one. Boston is at all times attractive, but particularly so in the early summer; and, however bent on knowledge the members of the association may be, it is safe to assume that their eyes are not wholly blinded to natural beauties. The gentlemen in charge of the recreation side of the meeting have chosen to have one of the sessions, with a luncheon, at the McLean Hospital in Waverly, and another at the Brookline Country Club. The meeting is being well attended, and the papers vigorously discussed. With a continuance of the present fair weather we trust the association may regard this meeting as a success, and Boston as one of its regular places of meeting,—a hope which we could express less warmly before the new medical library was prepared for the reception of guests. But with the availability of this library building we commend the example of the Pathological and Neurological Associations to the other national medical societies.

MEDICAL NOTES.

ADDRESS IN MEDICINE AT THE YALE MEDICAL SCHOOL.— The annual address in medicine at the Yale Medical School will be given on Tuesday, June 25th, by Prof. Edmund B. Wilson, Ph.D., of

Columbia University, on "The Higher Claims of Minute Research in Biology and Medicine."

Medical Excursion to London and Paris.— A medical excursion to London and Paris in connection with the Tuberculosis Congress in London, July 23 to 26, and the meeting of the British Medical Association at Cheltenham July 29 to August 2, 1901, occupying twenty-nine days, will leave New York July 10th, returning August 1st by way of Boston. The expense of the trip will be $238. There will be an alternative return for those who prefer waiting the adjournment of the British Medical Association, making a thirty-one day trip at a cost of $260. This trip has been carefully designed in the interests of medical men who desire to attend the two great medical meetings this summer in Great Britain. Before reaching their scientific work they enjoy the opportunity of spending several days in Paris for sight-seeing. In London they are quartered in one of the newest and largest hotels within easy reach of Westminster Abbey and the Houses of Parliament. In Cheltenham they find themselves in one of the most fashionable of English watering places.

Scholarship in Physiology at the University of Chicago.— By the will of the late Dr. Marie J. Mergler it is reported that the University of Chicago is to have a $3,000 scholarship in physiology.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, June 19, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 70, scarlatina 12, measles 147, typhoid fever 7.

Award of John W. Pray Prize.— The John W. Pray Prize offered by the trustees of the New Hampshire State Hospital for original work on any branch of medicine has been awarded to Dr. Albert E. Brownrigg for an essay on "The Clinical Significance of the Cheyne-Stokes Symptom-Complex." Dr. Brownrigg is a graduate of the Harvard Medical School of the class of '98, and is at present assistant physician at the New Hampshire State Hospital.

NEW YORK.

Gangrene of Intestine from Thrombosis.— At the June meeting of the Medical Association of the City of Greater New York, Dr. A. A. Berg presented the specimens from a rare case: gangrene of the intestine due to extensive thrombosis of the veins of the mesentery. The patient, a woman, was admitted to Mount Sinai Hospital three weeks after an attack of abdominal pain, coming on after lifting a heavy weight, and laparotomy was performed for apparent intestinal stenosis. There had been gradually increasing constipation, so that during the last week it had been impossible to secure any movement of the bowels whatever, and for three days before admission she had had stercoraceous vomiting. When the abdomen was opened there was found in the right iliac fossa a coil of enormously distended intestine about a foot in length, which was of a very dark color, and had a number of entirely black spots on its surface. The gangrenous portion of the intestine was resected, and an anastomosis made of the segments of healthy gut, but the patient survived the operation only a few hours. The thrombosis of the mesenteric veins, which had been detected during the operation, was fully demonstrated at the autopsy. Dr. Berg also presented the ovary of a patient operated on for pyosalpinx involving the appendix vermiformis. When admitted to the hospital she appeared to be suffering from an ordinary appendicitis with abscess formation; but when the abdomen was opened it was found that the case was really one of pyosalpinx, and that the appendix was involved only by continuity. The woman made a good recovery.

Commencement at Columbia University.— The one hundred and forty-seventh annual commencement of Columbia University was held on June 12th. There were 147 graduates in medicine, and the fellowships of the Alumni Association of the College of Physicians and Surgeons, $500 each, were awarded as follows: Fellow in anatomy, Dr. Henry E. Hale; fellows in pathology, Drs. Augustus B. Wadsworth and Charles Norris. The Alonzo Clark scholarship, $700, was awarded to Dr. Augustus J. Lartigan. Among the honorary degrees conferred was that of Master of Science, on Dr. George M. Lefferts, clinical professor of laryngology and rhinology in the College of Physicians and Surgeons. He was presented by Prof. T. Mitchell Prudden, who referred in fitting terms to Dr. Lefferts' twenty-five years' faithful and successful service in the college.

Horse Racing and Charity.— The $24,000 stakes won by the horse of James R. Keene, of New York, in the "Oaks" at Epsom, has been donated by the owner to charitable institutions in this country and in England. Among the gifts to New York charities were $2,000 to St. John's Guild and $1,000 each to the Herald Ice Fund and the Tribune Fresh-air Fund.

Bequest for a Laboratory.—It is announced that Prof. Henry Morton, president of the Stevens Institute, Hoboken, has given an additional $50,000 for the completion of the new chemical laboratory being erected at the college. His total gifts to the institute now amount to $140,000.

MORTALITY STATISTICS.—The reports of the Health Department show that during the month of May the mortality in the city represented an annual death rate of 18.26 against 20.67 in April and 19.88 in May, 1900. The weekly average of deaths from diphtheria and croup declined from 49.5 in April, to 44; from typhoid fever, 11.25 to 7.5; from pneumonia, 166.75 to 130.5; from phthisis, 177.5 to 150.25; from bronchitis, 42.25 to 31.75; from influenza, 17.5 to 5; from cancer, 51.25 to 41; and from diseases of the genito-urinary system, 124 to 102. The weekly average of deaths from smallpox increased from 9.25 to 13.75, and from scarlet fever, 43.75 to 44.5.

OPENING OF SEASIDE HOSPITAL OF ST. JOHN'S GUILD.—The Seaside Hospital of St. John's Guild at New Dorp, Staten Island, was opened for the season on June 15th, and on this occasion was dedicated the Lewis Memorial Cottage, which has been erected by Mrs. Frederick Elliott in memory of her son, Frederick Chandler Lewis. The new building, which cost $10,000, is a wooden structure 103 feet long and 35 feet wide, and contains two wards. It is designed for the care of the most serious cases of infantile disease, and is a complete hospital in itself.

ANNIVERSARY OF HOME FOR INCURABLES.—The thirty-fifth anniversary of the Home for Incurables at Fordham, borough of the Bronx, was celebrated on June 11th. It was announced that a gift of $30,000 had been received for the institution; and among the speakers on the occasion were Bishop Potter and Senator Chauncey M. Depew. The report of Dr. Israel C. Jones, the medical superintendent, showed that the death rate among the inmates was 19.5%. Of 30 patients discharged during the year, 4 were entirely cured.

BEQUEST TO A HOSPITAL.—Among the charitable bequests made by the widow of Martin B. Brown, who died recently, leaving an estate of $500,000, was one of $2,500 to St. Vincent's Hospital.

ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.—The certificate of incorporation of the Rockefeller Institute for Medical Research, of New York City, was filed with the Secretary of State at Albany on June 13th.

Miscellany.

THE MASSACHUSETTS MEDICAL SOCIETY. COUNCILORS' MEETING.

THE annual meeting was held in the Medical Library, Boston, on Tuesday, June 11, 1901.

The meeting was called to order at 5 P.M. by the president, Dr. Frank W. Draper. One hundred and twenty councilors were present.

The secretary read the names of 135 fellows admitted since the last annual meeting, and of 29 whose deaths had been recorded.

It was voted, on recommendation of the Committee on Membership and Finance, that $4,000 of the surplus in the treasury be distributed among the district societies.

The Committee on Publications reported that Dr. Frank Billings, of Chicago, has been appointed to deliver the Shattuck lecture at the annual meeting of the society in 1902.

Dr. H. R. Hitchcock called attention to the fact that the Massachusetts Medical Society many years ago had been instrumental in establishing a system of registration of births and deaths by the State. Of late years this has been much less satisfactory than formerly. He moved, and it was voted, that the following be referred to the Committee on State and National Legislation:

Resolved, That a committee of three experts shall be appointed by the Governor, whose duty it shall be to consider the subject of "registration of births, marriages, deaths and divorces, from the standpoint of efficiency, economy and practical usefulness," and shall report upon the same to the legislature not later than May 1, 1902, their report to include such recommendations and changes in the present plan as they may deem best.

The Committee on Nominations reported, and the following were chosen officers of the society for the ensuing year: President, Dr. Frank W. Draper, of Boston; Vice President, Dr. Augustus C. Walker, of Greenfield; Treasurer, Dr. Edward M. Buckingham, of Boston; Corresponding Secretary, Dr. Charles W. Swan, of Brookline; Recording Secretary, Dr. Francis W. Goss, of Roxbury; Librarian, Dr. Edwin H. Brigham, of Brookline. Dr. George S. Eddy, of Fall River, was chosen orator of the annual meeting of the society in 1902.

Voted, That the next annual meeting of the society be held in Boston on the second Wednesday in June, 1902.

The following standing committees were appointed:

Of Arrangements.—Drs. S. Crowell, W. H. Prescott, F. G. Balch, J. C. Hubbard, Farrar Cobb, A. P. Perry.

On Publications.—Drs. O. F. Wadsworth, Geo. B. Shattuck, H. L. Burrell.

On Membership and Finance.—Drs. E. G. Cutler, L. R. Stone, F. W. Goss, W. Ela, C. M. Green.

To Procure Scientific Papers.—Drs. A. K. Stone, C. F. Withington, W. H. Pomeroy, J. B. Blake, G. L. Richards.

On Ethics and Discipline.—Drs. G. E. Francis, F. C. Shattuck, C. G. Carleton, E. Cowles, J. F. A. Adams.

On Medical Diplomas.—Drs. H. E. Marion, E. N. Whittier, O. F. Rogers.

On State and National Legislation.—Drs. F. W. Draper, H. P. Bowditch, S. D. Presbrey, S. W. Abbott, B. H. Hartwell.

Obituary.

WILLIAM LEONARD WORCESTER, M.D.

WE regret to record the death of Dr. William L. Worcester, for six years physician and pathologist at the Danvers Insane Hospital. He died Sunday, June 5th, at the age of fifty-six, after a brief illness, from septicemia.

He was born in 1845 in Chelsea, Vt., and obtained his primary education in the public schools of Thetford of that State. His father, Ezra C. Worcester, was a physician before him, and the son decided to undertake the same profession. After graduating from Dartmouth College in '69, he went to Washington, D.C., and was for a time clerk of the senate committee on pensions. He obtained his degree of doctor of medicine from a medical school in Washington, and was then appointed medical examiner in the pension department. After further study in Europe, and after engaging in private practice for a few years in Burlington, Vt., he decided to adopt mental diseases and pathology as his special field of work. He was for eleven years assistant physician at Kalamazoo, Mich., and for six years assistant superintendent at the insane hospital at Little Rock, Ark. He came to the Danvers Hospital in 1895.

As an alienist and pathologist Dr. Worcester had made for himself an enviable position among his colleagues and those best fitted to judge of his scholarly qualities. He was an unassuming man, quiet in manner, and not inclined to force himself upon the attention of others. In spite of this fact he accomplished in his laboratory researches a most creditable amount of work, always carefully thought out and considered before being submitted to the printer. Although he had much knowledge of general pathology, he had latterly devoted himself especially to the difficult field of the pathology of the nervous system, and had published many papers of decided merit and originality. It is not too much to say that he was one of the pioneers in the application of modern microscopic technique to the nervous system in America, a department of research in which it was natural that good work should have long gone unrecognized.

His death is a loss to the profession at large, and especially to the Danvers Hospital, with which he had become closely identified. The hospital, no doubt, owes him more than can at present be realized, for he represented the best tendency in psychiatrical research. In addition to his knowledge of mental disease he was an excellent neurologist, and a man of high scholarly attainment. He was a member of the American Neurological Association, and a faithful attendant at its meetings. Within a few months he had read a paper before the newly formed American Association of Pathologists and Bacteriologists.

Dr. Worcester leaves an aged mother, three brothers and three sisters, who were present at his bedside when he died, with the exception of one brother, Dean C. Worcester, of the Philippine commission, who is now at Manila.

Correspondence.

SMALLPOX AT BERLIN.

NEW HAMPSHIRE STATE BOARD OF HEALTH.

CONCORD, N. H., June 12, 1901.

MR. EDITOR: In response to numerous inquiries, and to inform the public generally on the smallpox situation at Berlin, we have to say that there are at this date, June 12th, approximately 36 cases of the disease in northern New Hampshire; 2 cases in a lumber camp on Gale River, 2 cases in one family at a farmhouse in Berlin, and 32 cases in the isolation hospital in that city. All of these cases are under strict quarantine, and in no manner whatever endanger the public.

An order is for the present in force in the city of Berlin making it a penal offense not to report to the Board of Health every form of eruptive disease. A competent and experienced inspector of the State Board of Health, with headquarters at Berlin, has supervision over the situation, and is co-operating with the local boards of health in carrying out such restrictive measures as may be necessary. No effort is being spared by the State and local authorities to stamp out the disease at the earliest possible moment.

The malady is, of course, confined to the unvaccinated classes. Extensive vaccination has, however, been brought about by the co-operation of health officers, ministers, priests, manufacturers and public sentiment. The situation, therefore, should not cause public alarm, and there should be no interference with business or travel.

There is no occasion whatever for any quarantine to be established other than that now in force, covering the cases themselves, and any quarantine that may have been established by any town against free communication, travel, or business, is hereby dissolved by authority conferred upon this board by the Public Statutes.

We urge upon every town and city the great importance of general public vaccination, and reiterate our recommendation that lumbermen, manufacturers and others require that successful vaccination shall be one of the requisites for employment.

We repeat that the situation should not cause alarm, but that every community and every individual should avail themselves of the only known preventive of smallpox, to wit: vaccination.

We shall keep the public fully informed regarding the situation, and no credence should be given to the baseless rumors that are not infrequently circulated.

IRVING A. WATSON, M.D., *Secretary.*

INHERITED PREDISPOSITION TO APPENDICITIS.

61 Auburndale Place,
CINCINNATI, June, 1901.

MR. EDITOR: I am trying to establish the fact, which I believe from my own personal observation to be true (see *Lancet Clinic*, June 8th), of an inherited tendency or predisposition to appendicitis. If the readers of your journal will kindly look into history (family) of their cases and report to me, I will be under very many obligations.

Truly yours,
W. H. DEWITT, M.D.

METEOROLOGICAL RECORD.

Newburyport	14,478	3	—	33.33	—	—	—	—
Melrose . .	12,962	—	—	—	—	—	—	—

Deaths reported 2,410, under five years of age 696; principal infectious diseases (smallpox, measles, scarlet fever, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 592, acute lung diseases 256, consumption 329, scarlet fever 13, influenza 1, erysipelas 15, typhoid fever 23, whooping cough 18, measles 19, cerebro-spinal meningitis 7, smallpox 19.

From whooping cough, New York 5, Philadelphia 7, Baltimore 1, Providence 1, Boston 1, Holyoke 2, Quincy 1. From cerebro-spinal meningitis, Philadelphia 1, Lynn 2, Fall River, New Bedford, Somerville and Brockton 1 each. From scarlet fever, Philadelphia 5, Boston 5, Brookline 2, Chelsea 1. From typhoid fever, New York 5, Philadelphia 12, Baltimore 1, Providence 1, Boston 2, Salem and Newburyport 1 each. From erysipelas, New York 6, Philadelphia 3, Baltimore 3, Lowell, Medford and Southbridge 1 each. From smallpox, New York 16, Philadelphia, Providence and New Bedford 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,463,187 for the week ending May 25th the death rate was 16.7. Deaths reported 3,674: acute diseases of the respiratory organs (London) 191, whooping cough 120, diphtheria 55, measles 96, fever 28, scarlet fever 38.

The death rate ranged from 11.2 in Croyden to 22.6 in Wolverhampton; Birkenhead 17.4, Birmingham 21.8, Blackburn 14.3, Bolton 18.2, Bradford 19.5, Brighton 12.6, Bristol 13.6, Burnley 20.4, Cardiff 15.8, Derby 17.2, Gateshead 17.5, Halifax 18.8, Huddersfield 13.7, Hull 15.8, Leeds 15.3, Leicester 15.0, Liverpool 19.3, London 15.7, Manchester 18.5, Newcastle-on-Tyne 18.1, Norwich 12.1, Nottingham 19.5, Oldham 16.7, Plymouth 16.4, Portsmouth 16.2, Preston 17.1, Salford 22.1, Sheffield 16.4, Sunderland 15.9, Swansea 21.5, West Ham 14.7.

CHANGES IN THE MEDICAL CORPS OF THE NAVY WEEK ENDING JUNE 8, 1901.

Doctors J. W. Backus, F. A. Asserson, J. F. Murphy, W. Seaman and R. R. Richardson, appointed assistant surgeons in the Navy.

F. J. B. Cordeiro, surgeon. Detached from the "Buffalo," June 10th, and ordered home to wait orders.

L. W. Curtis, surgeon. Ordered to the "Buffalo," June 10th.

E. S. Bogert, Jr., passed assistant surgeon. Commissioned surgeon from December 15, 1900.

R. W. Plummer, assistant surgeon. Detached from the "Nashville" and ordered to the "Princeton."

W. Seaman, assistant surgeon. Ordered to the "Independence," June 17.

H. H. Haas, assistant surgeon. Detached from Naval Hospital, New York, and ordered to the Norfolk Navy Yard, June 10th.

R. R. Richardson, assistant surgeon. Ordered to Naval Hospital, New York, June 10th.

J. M. Brister, assistant surgeon. Detached from the "Independence" June 17, and ordered to the Asiatic Station via Transport "Hancock."

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 30, 1901.

CARTER, H. R., surgeon. To inspect the local quarantine station at Baltimore, Md. May 25, 1901.

WOODWARD, R. M., surgeon. Granted two weeks' extension of leave of absence from May 28. May 25, 1901.

VAUGHAN, G. T., surgeon. Detailed as delegate to represent the service at the meetings of the Association of Military Surgeons of the United States May 30; and American Medical Association June 4, at St. Paul, Minn. May 27, 1901.

COBB, J. C., passed assistant surgeon. Relieved from duty at Fort Stanton, N. M., and directed to proceed to Portland, Ore. May 29, 1901.

WERTENBAKER, C. P., passed assistant surgeon. Detailed to represent the service at meeting of the Association of Military Surgeons of the United States May 30; and American Medical Association, June 4, at St. Paul, Minn. May 27, 1901.

GARDNER, C. P., passed assistant surgeon. Detailed to represent service at meeting at the Washington State Medical Society at Seattle, Wash., June 18 to 20, 1901, inclusive. May 27, 1901.

DECKER, C. E., assistant surgeon. Granted leave of absence for ten days. May 28, 1901.

HOBDY, W. C., assistant surgeon. To proceed to Thomson, Ga., for special temporary duty. May 27, 1901.

HARGIS, J. W., acting assistant surgeon. Granted leave of absence for four days from May 28. May 27, 1901.

OLSEN, E. T., hospital steward. Granted leave of absence for fifteen days from June 13. May 22, 1901.

SPANGLER, L. C., hospital steward. To proceed to Delaware Breakwater, Del., and report to medical officer in command for duty and assignment to quarters. May 28, 1901.

APPOINTMENT.

Lewis C. Spangler, of Ohio, appointed junior hospital steward in the U. S. Marine Hospital service. May 27, 1901.

RECENT DEATH.

DR. DANIEL W. MARSTON, of New York, recently died at Schenectady, N. Y., having been taken with pneumonia while on his way to the meeting of the American Medical Association at St. Paul. He was graduated from Bellevue Hospital Medical College in 1898.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the Associated Physicians of Long Island, January, 1900, to June, 1901. Vol. II.

Mosquitoes. How They Live; How They Carry Disease; How They are Classified; How They may be Destroyed. By L. O. Howard, Ph.D. Illustrated. New York: McClure, Phillips & Co. 1901.

Etidorhpa, or the End of Earth; the Strange History of a Mysterious Being and the Account of a Remarkable Journey, by John Uri Lloyd, author of "Stringtown on the Pike." Illustrated. New York: Dodd, Mead & Co. 1901.

Progressive Medicine, a Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., assisted by H. R. M. Landis, M.D. Vol. II. June, 1901. Illustrated. Philadelphia and New York: Lea Brothers & Co.

Original Articles.

A STUDY OF THE FOOD CONSUMED AND DIGESTED BY FOUR MEMBERS OF THE HARVARD UNIVERSITY BOAT CREW IN JUNE, 1900.

BY W. O. ATWATER AND F. G. BENEDICT, WESLEYAN UNIVERSITY.

(Concluded from No. 25, p. 606.)

The figures of Table 5 imply that the quantities of food eaten by the Yale and Harvard crews varied within comparatively narrow limits. The quantities were regulated mainly by the appetites and instincts of the eaters, as is the case generally with people who have all they want to eat. Well-to-do people of sedentary habits are often inclined to eat more than they need or than is best for them. It seems probable that people with severe muscular work and plain diet would be less prone to dietary excess. It is evident that these college crews had instinctively arrived at a standard which was nearly uniform for all. Whether that standard, with its 154 grams of protein and fuel value of 3,925 calories in the food actually eaten, is the best for men of their class, and the work they have to do is a question that cannot be decided without a great deal of careful observation and painstaking experiment.

THE DIGESTION EXPERIMENTS.

The object of the digeston experiments is to find what proportions of the food as a whole, and of its several constituents, are digested and made available to the body for building and repair of its materials and for the yielding of energy. A large part of what is definitely known of this particular subject comes from late German inquiry, the methods and results of which have not yet received great attention in American and English medical literature. In the co-operative inquiry referred to above as carried on in different parts of the United States, considerable experimenting has been done in this direction during the past few years.

Definitions of terms.—The following statement, condensed from a late article on the subject,[17] will explain the use of the terms digestibility, availability, energy and fuel value in the present article.

The digestion of food is done at the expense of a certain amount of material which other food has supplied, and which has been fitted by the body for the particular purpose. This material is essentially that which is poured into the alimentary canal in the digestive juices. That which is not reabsorbed remains in the feces in the so-called metabolic products. These latter include, also, the fragments of intestinal epithelium and minute quantities of other substances.

In addition a small part of the food escapes digestion. The feces are, accordingly, made up of (1) metabolic products which are mainly the residues of digestive juices, and (2) the undigested residues of the food. This brings out the distinction between the terms digestibility and availability as they are here used.

Digestibility of food.—This term is here used to designate the quantity or proportion of material actually digested. It is measured by the difference between the total food and the undigested residue. The statement applies likewise to the several nutrients — protein, fats, carbohydrates and mineral matter. To determine what amount of each is digested, the total amount in the food and the corresponding amount of undigested residues in the feces should be determined. Subtracting the undigested residue from the total amount would give the amount digested. The methods for distinguishing between the metabolic products and the undigested residue of the food, however, have not been made sufficiently accurate to enable us to determine exactly the amounts of undigested residue in the feces. Hence satisfactory determinations of digestibility, in the sense in which the word is here used, are yet hardly feasible.

Availability of food.—The term availability is here used to designate the quantity or proportion of the food and of each of the several nutrients which can be used for the building and repair of tissue and the yielding of energy. The metabolic products are not used either for building material or fuel, and hence are not available in the sense in which the word is here employed. They represent part of the cost of digesting the food. The amounts of available nutrients are found by subtracting the sum of the metabolic products and the undigested residue; that is, the ingredients of the feces, from the corresponding ingredients of the food. The term digestible has often been used in the sense in which available is here employed, but the distinction here made is evidently an important one. How the available nutrients of the food are actually utilized in any given case; how much benefit the body gains from a given amount of nutrients in any given diet, is another matter.

Energy.—The total energy of a given quantity of food or body material is taken as equivalent to its heat of combustion in oxygen as measured by the bomb calorimeter, the unit of measurement being the large calorie. This assumes that when material is oxidized in the body the amount of latent energy which becomes kinetic and available to the body is the same as if the material were oxidized to the same or equivalent products outside the body; for example, in the bomb calorimeter. The correctness of this assumption is based upon the belief that the law of the conservation of energy holds in the living organism, and is verified by the results of late experiments with men in the respiration calorimeter at Wesleyan University.

Available energy.—The view thus expressed makes the total available energy of the food the total energy (heat of combustion) less that of the corresponding unoxidized residues of the feces and urine. It is also the total energy of the available nutrients less that of the corresponding unoxidized material of the urine.

[17] Discussion of the terms Digestibility, Availability and Fuel Value, by W. O. Atwater. Report of Storrs (Conn.) Experiment Station, 1899, p. 69.

Fuel value.— This term is here used synonymously with available energy; that is, it signifies the energy of the material of the food which is oxidized (that is, capable of oxidation) in the body. For the protein it is the total energy less that of the corresponding unoxidized residues of the feces and urine. For the fats and carbohydrates it is the total energy less the energy of the corresponding unoxidized material of the feces.

The term fuel value is also applied, in the same signification, to the body materials oxidized.

TABLE 6.— FECES: FOUR ATHLETES, 7 DAYS. DIGESTION EXPERIMENT NO. 191.[1]

Laboratory No.	Subject.	Day of Study. 1	2	3	4	5	6	7	Total. 7 Days.

[1] As these weights include water, they are of minor importance.

Coefficients of availability.— The difference between the income of each ingredient in the food and the outgo in the feces shows the amount available. The coefficients of availability of nutrients are found by dividing the amounts available by the total amounts in the food. The same principle applies in estimating the available energy, which is the total energy of the food less that of the feces and urine, and is here taken as the measure of the fuel value. The coefficients of availability of the energy of the food and of the several kinds of nutrients are found by dividing the available by the total energy.

Results of the digestion experiment.— The weights of feces are given in Table 6 and the composition in Table 2. The weights and composition of the urine are stated in Table 9. Table 7 summarizes the results of the digestion experiment. The figures for food eaten per man per day are taken from Table 4; those for feces are calculated from the amounts and the composition.

It will be remembered that the amounts of food eaten by the four men collectively were weighed each day, no attempt being made to learn just how much each individual man ate. The amounts of feces excreted by each individual during the whole seven days were weighed, so that the amounts for each were determined separately.

The figures for feces per man per day are found by taking the total intestinal excretion of each man for seven days, as computed from Tables 2 and 6 and dividing by 7; this gives the averages per day for each of the four men in Table 7. The averages of these four individual averages are taken as the general averages per man per day in Table 7.

The figures for the heats of combustion of food and feces are calculated from the results of actual determinations with the bomb calorimeter. The energy lost in the urine in like manner represents the heats of combustion of the unoxidized materials of the urine.

The amounts of available nutrients are obtained by subtracting the quantities in the feces from those in the food. The corresponding figures for energy are found by subtracting the sum of the heats of combustion of the unoxidized materials of feces and urine from the total heats of combustion of the food. The coefficients of availability for both nutrients and energy are obtained by dividing the amounts available by the total amounts.

According to the figures of the table, 92.5% of the nitrogen and 92.2% of the protein of the food are available to the body. This slight difference is explained by the fact that the factors used for computing the protein from the food differ somewhat in the different food materials, as explained in Table 8 beyond. The discrepancy is of no practical consequence.

Availabilities of nutrients and energy of food.— The main result of the experiment is found in the coefficients of availability. According to the figures of Table 6 these four athletes in the last days of active training for the boat race, on a simple and ample diet digested their food so as to make the following proportions of the several constituents available to their bodies for the building and repair of tissue and the yielding of energy:

Protein	92.2%
Fats	95.6%
Carbohydrates	98.1%
Energy	91.8%

Two questions naturally occur. The first is: Was there any considerable difference in the pro-

portions of food digested by individual men? The second is: Did these men, with severe muscular exercise for about three hours each day and a diet which supplied, on the average, 154 grams of protein and 3,926 calories of energy per day, digest their food, on an average, more or less completely than do men in ordinary occupations with ordinary diet?

Average coefficients of availability.— There are now on record the results of nearly 200 American digestion experiments with men, mostly with mixed diet, and perhaps an equal or larger number of European experiments with single food materials and mixed diet. From the data thus obtained factors have been derived [18] which represent more or less nearly the average coefficients of availability of the nutrients of different kinds of food materials when eaten by ordinary men in health and at ordinary occupations. In working out these coefficients for availability food materials were divided into the following groups:

(1) Animal food materials, as meats, fish, milk, eggs, etc.
(2) Cereals, such as wheat, rye, barley and buckwheat flours, corn (maize) meal, etc.
(3) Sugars and starches.
(4) Vegetables, as potatoes, cabbage, turnips, etc.
(5) Fruits.

Referring to the original discussion for explanations we give the coefficients in Table 8, and with them the nitrogen factors for protein referred to above.

TABLE 8.— FACTORS FOR COMPUTING PROTEIN FROM NITROGEN AND COEFFICIENTS OF AVAILABILITY OF NUTRIENTS OF DIFFERENT GROUPS OF FOOD MATERIALS.

	Nitrogen factor for Protein.	Coefficient of Availability.		
		Protein. Per cent.	Fat. Per cent.	Carbohydrates. Per cent.
Animal food	6.25	97	95	98
Wheat, rye, barley, and their manufactured products	5.70	85	90	98
Maize, oats, buckwheat, rice, and their manufactured products	6.00			
Dried seeds of legumes	6.25	78	90	97
Sugars and starches				98
Vegetables	5.65	83	90	95
Fruits	5.80	85	90	90

The accuracy of these assumed coefficients of availability can be tested by the results of actual digestion experiments. This may be done by taking the diet used in a given experiment, computing the amounts of available nutrients by use of these assumed coefficients, and comparing the results with those of the actual experiments. In the average of 93 American experiments, in which the computed quantities of available nutrients were compared with those actually found by experiment, the following results were obtained: [19]

[18] The Availability and Fuel Value of Food Materials, by W. O. Atwater and A. P. Bryant, Report of Storrs Experiment Station, 1899, p. 73.

[19] Atwater and Bryant, Report Storrs Experiment Station, 1899, p. 87.

AVAILABILITY OF NUTRIENTS OF ORDINARY MIXED DIET.

	Protein. Per cent.	Fats. Per cent.	Carbohydrates. Per cent.
Computed by use of coefficients	93.6	94.5	98.1
Found by actual experiment	93.3	95.8	98.7

While it is not to be supposed that the coefficients given in Table 8 represent the actual availability of the nutrients of the different kinds or classes of food materials under all circumstances, the close agreement between results found by experiment and computed by these factors does imply that they represent a fairly close approximation to the actual availability in the average mixed diet of ordinary people in health.

This brings us to the question whether the availability of the food as digested by the four athletes in the present experiment agreed with that of the food eaten by men at ordinary occupations. By applying the coefficients of availability of Table 8 to the diet of the athletes, we can find what proportions of the total nutrients would probably have been made available if the same kind of foods had been eaten by men at ordinary occupations. Comparing the coefficients as thus calculated with those found in the experiments with the athletes, will show the agreement or disagreement. The results follow:

AVAILABILITY OF FOOD EATEN BY FOUR ATHLETES.

	Protein. Per cent.	Fats. Per cent.	Carbohydrates. Per cent.	Energy. Per cent.
Computed by use of coefficients of availability with ordinary men	93.7	94.2	97.1	91.0
Found by actual experiment with athletes	92.2	95.6	98.1	91.8

It will be remembered that the diet of the athletes furnished on the average 154 grams of protein, and had a fuel value of 3,925 calories, while in the diet of men at ordinary occupations the protein would not have averaged much over 100 grams, or the fuel value much over 3,300 calories per man per day.

It would thus appear that the athletes obtained just about the same proportions of available nutrients from their food as do men at ordinary occupations. This is equivalent to saying that the athletes on the average digested their food just about as completely as the average man does.

Differences in the digestion of food by the four individual men.— The above statements apply to the average results with the four men. The figures of Tables 6 and 7 bring out a striking difference in the amounts of nutrients rejected in the feces by the different subjects. The total

weights of the feces varied from 105 grams per day with A to 248 grams with D. The variation in the organic matter, from 21 to 35 grams per day, is somewhat smaller. The nitrogen varied from 1.3 grams per day with A to 2.3 grams with D, which is again a very wide difference. The range in the fats, from 4 to 11 grams, is in still wider proportion. With the carbohydrates on the other hand, the quantities are nearly alike. These differences may be explained on either of three suppositions:

(1) A may have eaten much less food than D. This is possible, but seems hardly probable. Actual observation at the time gave the impression that A ate fully as much as the others, and that if any one ate noticeably less than the rest, it was C; but of course no exact weighings of the quantities served each man were made.

(2) In the digestion of the food by A much smaller quantities of digestive juices may have been secreted than in the case of D.

(3) A may have a power of digesting food much more completely than D.

It may be that two or perhaps all three of these causes united to bring about the differences noted. The quantities of organic compounds and of energy in the feces per day come much nearer to the general averages with B and C than with A and D.

So far as this particular experiment is concerned, it is greatly to be regretted that the circumstances did not permit of separate determinations of the amounts of food eaten by each of the subjects. Such determinations would have shown the exact proportions of available and unavailable nutrients for each man. It would be interesting to know whether there was any difference in the physical conditions of the subjects corresponding to the apparent differences in the digestion of the food.

Two further points should be noted. The first is that on Sunday, June 24th, no work was done, and the amount of food eaten was less than on other days. It is hardly to be supposed, however, that this fact would materially affect the percentage of organic residues in the feces; still in estimating the digestibility and availability of food eaten during intense work, it would be more satisfactory to use the data for working days only. In this case the feces corresponding to the food of Sunday could not well be distinguished from the rest.

The second is the wide variation in the amounts of feces in the individual days, as shown in Tables 6 and 7. This illustrates the importance of extended and repeated experiments of this kind for obtaining reliable averages.

Importance of examining feces of men in training.— The feces were examined macroscopically at each collection. It was expected that with the large appetites of men with such severe muscular exercise and with the habit of rapid eating so common to athletes, that a not inconsiderable portion of the food, especially meats, would be swallowed so rapidly as to escape proper mastication. This rapid eating we have observed with athletes elsewhere.

On one day in this experiment the men ate canned corn at the evening meal. The next day all four had a marked diarrhea, and the feces contained undigested kernels of corn. These appeared in one case in less than twelve hours and in others within twenty-four hours after the ingestion. Thereafter canned corn was avoided. Here is an instance where an observation of a kind commonly neglected was of great practical importance.

In every way other than that just mentioned the feces appeared normal, and no large particles of undigested food were observed. We were told that the men had been advised to eat slowly and masticate their food well.

The above considerations lead to two suggestions; one is as to the desirability of the examination of feces of men in training, in order to detect indications of imperfect digestion and other irregularities. This has to do with the health and welfare of the men in training, and interests the attendant physician and the trainer. The other is the desirability of microscopical and chemical studies of the feces of athletes in training, for the purpose of obtaining information of possible value regarding the general effect of diet. This is a matter for the physician and the physiological chemist.

AMOUNT AND COMPOSITION OF URINE.

The urine from each subject was collected separately, and the nitrogen, urea, uric acid and heat of combustion of the dried residue of the urine were determined for each day of the experiment. The statistical results are shown in Table 9.

Quantities of total urine and constituents.— The most noticeable feature of the data in this table is found in the very small quantities of total urine and of the constituents determined. This is particularly marked in the case of A on the last two days, B on the last day and C on the third, fourth and sixth days. The quantities of total nitrogen, urea and uric acid and the heat of combustion are correspondingly small with the same subject on the same day. The question of the small daily excretion of nitrogen in the urine will be touched upon in the discussion of the income and outgo of nitrogen.

Urea and uric acid.— The ratio of these constituents in the urine does not differ sufficiently from day to day to warrant any inferences as to the effect of either the diet or the exercise upon their elimination. A considerable amount of labor was devoted to the determinations of urea and of uric acid along with those of the total nitrogen, in the hope that the data thus obtained might possibly throw some light upon the general question of the relation between their amounts and the amount and severity of the exercise taken. Despite the interest taken in this phase of the subject by Dr. Brown, and the detail and accuracy of the determinations of urea and uric acid made by him, the conclusions warranted are

more negative than positive. It is hoped, however, that the results here obtained, together with the results of other investigations which have been collected by Dr. Brown, may be published in another place.

There was a loss of urine from one of the subjects, C, on the sixth day, which was Sunday. He feels positive, however, that the amount which thus failed of collection was small, and that at no other time did such an oversight occur. Each of the other subjects is certain that there was no such loss in his own case. An attempt has been made to correct the figures for C on the sixth day in the following way: The average daily excretion of nitrogen in the urine by A, B and D for the six days, exclusive of the sixth, was 20.2 grams, and the amount on the sixth day was 17.6 grams. The quantity excreted by C on the other six days averaged 18.9 grams per day. Assuming that for C the ratio of the quantity for the sixth day to the average quantity for the other days would be the same as the average ratio for the other three men, the quantity of nitrogen excreted by C on the sixth day would be found by the proportion 20.2 : 17.6 18.9 : x (=16.5). Assuming the percentages of nitrogen and other ingredients and the specific gravity of the whole urine of C for the sixth day to be the same as in the 822 grams actually saved and analyzed, the figures would be as given in Tables 9 and 10.

NITROGEN BALANCE.

In striking a balance of income and outgo of nitrogen, it is customary to subtract the amount in the feces and urine from the amount in the food each day. The figures thus obtained in this experiment are given in Table 10, and show a gain of body nitrogen each day. The average gain per man per day is thus computed to be: Nitrogen 3.9 grams, protein 24 grams.

These estimates of amounts excreted are affected by three errors, each of which tends to diminish the estimate of amount of nitrogen excreted, so that the figures in the table make the amount of nitrogen stored in the body larger than was actually the case.

[1] Corrected for probable loss. The actual amount of urine was 822 grams. See this page.

The first error was due to an actual loss of urine from one of the subjects, C, on the sixth day. A correction for this was made in the figures of Table 9, which are used in Table 10.

The second serious loss is in the drying of the feces for preparation for analysis. This results in the volatilization of a small amount of nitrogenous material. Experience in this laboratory leads us to believe that this amount will not much exceed .1 gram in the total feces per man per day.[20] This error is so small as to be usually neglected, and no allowance is made for it here. Even if it were as high as .2 of a gram of nitro-

[20] See page 21 of Bulletin 69 of the Office of Experiment Stations, U. S. Department of Agriculture.

gen, it would make an error of only 1.25 grams of protein per man per day.

The third loss is in the nitrogenous compounds thrown off from the body in the water of perspiration, and may be of more consequence. Schäfer[21] cites various determinations of the quantity of urea and nitrogen excreted in the water of perspiration. Thus Favre found .044 grams urea per 1,000 cc. perspiration, and Funke 1.55 grams urea in 1,000 cc. of perspiration. Argutinsky found .363 and .410 grams of urea in 225 and 330 cc. of perspiration respectively. The same investigator also found .7 of a gram of nitrogen by extracting with distilled water the clothes worn by subjects actively walking or climbing during a considerable portion of the day. C. C. Esterbrook[22] found, in some experiments upon himself, that the perspiration contained from .1 to .3 per cent urea. In experiments with the respiration calorimeter,[23] in which the subject worked upon a stationary bicycle for eight hours each day, the amount of nitrogen found in the clothes by extraction with distilled water varied from .2 to .4 of a gram per day.

A still more pronounced elimination of nitrogen in the perspiration was found by Eikjnamn[24]

in three experiments with Malay medical students in the tropical climate of Java. The first experiment lasted three hours, during which .222 gram of nitrogen was excreted. The second experiment continued twenty-four hours, during which time there was found in the perspiration .761 gram of nitrogen. The third experiment likewise continued twenty-four hours, and there was an elimination of nitrogen in the perspiration amounting to 1.362 grams. The subjects were engaged in light occupation.

It will be noticed that the largest quantity of nitrogen excreted in the perspiration in any of the instances above cited, was with men with light bodily exercise in the very warm climate of Java. This was estimated at from .8 to 1.4 grams per day. The excretion of perspiration by the members of the crew in the periods of practice is very profuse, as may be understood when we consider that the total loss of weight during a row of from twenty to thirty minutes reaches as high as three or four pounds. How much nitrogen is contained in this perspiration we have no means whatever of determining.

If we were to take the loss of nitrogen in drying the feces at .1 and that in the perspiration at 1.9, we should have a total average of 2 grams, which would correspond to 12.5 grams of protein. This would reduce the gain of protein as indicated by the figures of Table 10, from 24 grams to 11.5 grams, or a little over one-third of an ounce[25] per man per day. Assuming the fat-free muscular substance to be one-fourth protein and three-fourths water, this would correspond to 46 grams, or a little over 1½ ounces of muscular substance daily. Such a gain of protein suggests two lines of queries. (1) Does the gain of nitrogen indicate an undesirable bodily condition? Is a man in the best physical condition for severe muscular strain when his body is gaining protein so rapidly? Does not ripeness of muscular development require that the body shall have attained approximate protein equilibrium? Could such a lack of nitrogen equilibrium have anything to do with staleness? How much stress is to be laid upon these questions we do not presume to judge, still less would we assume to say that the figures of Table 10 prove that the men were not in the best training. Least of all would we affirm a connection between nitrogen balance and tendency to staleness. But we do consider the subject of sufficient interest to call for further study. (2) Was the amount of protein found in the study excessive? The figures of Table 5 (page 605) compare the quantities of nutrients in the food of the athletes in these experiments with the food of other athletes and of men at ordinary occupations. It is noticeable that all of the dietaries of men subject to intense muscular strain supply large quantities of protein as well as energy. Indeed, the proportion of proteids to fats and carbohydrates is larger than in the diet of people at ordinary occupations.

Tradition in athletic quarters says that a man cannot "get into condition" without eating large quantities of meat, and especially of lean meat. It appears to be a general usage of athletes and prize fighters in Europe and the United States to eat large quantities of nitrogenous food. How generally this is true in Asiatic countries the statistics we have been able to find do not fully explain. The theory suggested by Zuntz[26] that intense muscular effort involves a large protein supply seems intrinsically rational, and is supported by a large amount of evidence. It is, however, a question whether the amount of protein eaten by these athletes was or was not the most appropriate.

In this connection the apparent usefulness of sugar as a supplementary food for men subjected

to an intense muscular strain, is worthy of notice. The experiments of Stovis,[27] Zuntz and Schumburg,[28] Prantner and J. Stowasser[29] and others, as to the beneficial value of sugar in muscular work has had practical corroboration in experiments made on a large scale on certain Dutch rowing clubs[30] and on soldiers.[31] We do not presume to make any suggestions concerning the value of sugar as an article of diet during training, but the results cited above would seem to indicate that the question is at least worthy of consideration and careful investigation.

SUMMARY.

In June, 1900, a study was made of the actual amounts and composition of food eaten by four members of the Harvard University crew during one week of active training immediately preceding a race. The data obtained also include the statistics of the quantity and composition of solid and liquid excreta during the same period. The investigation thus included a dietary study, a digestion experiment, a study of the excreta, and a nitrogen metabolism experiment.

Dietary study.— The four men ate on the average 154 grams of protein, 139 grams of fat and 473 grams of carbohydrates, with a fuel value of 3,925 calories per man per day. These results compare with those of other studies as follows:

Protein and Energy in Food per Man per Day.

	Protein.	Energy.
	Grams.	Calories.
Four men of Harvard University crew, New London, 1900	154	3,925
Harvard University crew, New London, 1898.	160	3,945
Average, Harvard and Yale University and Freshmen crews, Cambridge, New Haven and New London, 1898	155	3,965
Average, 38 dietaries of men at ordinary occupations, United States	102	3,310

It thus appears that the four men ate just about as much as the Harvard and Yale crews in 1898, and that their food had about 50% more protein and 16% more energy than that of the men at ordinary occupations in the United States whose dietaries have been studied.

Digestion experiments.— Comparison of the amounts of nutrients in the food with those in the solid excreta shows the amounts that were actually available. These are nearly, but not quite, the same as the amounts actually digested. They differ from the latter by the amounts of metabolic products in the feces. The average coefficients of availability in these digestion experiments were:

Protein	92.2%
Fat	95.6%
Carbohydrates	98.1%
Energy	91.8%

These figures are very nearly identical with those obtained by taking the coefficients of availability of food as found by experiments with men on ordinary diet and at ordinary occupations, and applying them to the diet of the men in the present experiments. This means that the four athletes, on the average, digested their food just about as completely as the average man does. There were, however, marked differences in the amounts and composition of the feces of the different men, such, indeed, as to imply wide differences in their capacity to digest their food.

Studies of the excreta.— No especial studies were made of the composition of the feces. Comparisons of the urea and uric acid in the urine failed to bring any results such as to warrant conclusions regarding the effect of severe muscular exercise upon their amounts.

Nitrogen balance.— One notable feature of the experiments was found in the fact that the nitrogen excreted by the kidneys and intestines was considerably less in amount than the total nitrogen of the food. This means that there was a considerable storage of nitrogen in the body. The amount was such as to correspond to an average of not far from 24 grams of protein per day, if no allowance is made for the excretion of nitrogenous compounds in perspiration through the skin. Even after making allowance for a very considerable excretion of nitrogen through the skin, this gain is so noticeable as to suggest the queries whether men who are storing nitrogen to such extent are in the best physical condition, and whether the amount of protein in the diet was the most appropriate for the purpose.

Need of further research.— Perhaps the most important conclusion to be derived from the experiments is that further and more detailed investigations are needed to show what diet is best for men under such severe muscular strain as that of oarsmen in training for races.

SOME FORMS OF INTESTINAL OBSTRUCTION DUE TO ADHESIONS.[1]

BY A. T. CABOT, M.D., BOSTON,

Surgeon to the Massachusetts General Hospital.

It is not my purpose to consider in this paper the subject of internal strangulation behind bands, but rather to present the results of some personal experience in cases where, as the result of extensive adhesions, the functional activity of different parts of the alimentary canal has been interfered with.

Adhesions may cause this sort of interference with the functions of the stomach and intestines by limiting the motility of these organs that require the greatest freedom of motion, or by holding them in such awkward, twisted positions that the passage of their contents is impeded. Such an interference with the functions of the stomach is often seen as a result of adhesions following inflammations about the gall bladder and the pancreas, or occurring as a secondary effect of ulcers of the stomach or duodenum. These

[1] Read before the Surgical Section of the Suffolk District Medical Society, February 6, 1901.

conditions are of great importance, and give rise to manifold symptoms which well repay close study. This is, however, a chapter of the surgery of the stomach, which I do not propose to enter upon here, for it would open up a wider subject than I propose for myself in this brief paper.

I shall confine myself here to certain chronic conditions of obstruction in the intestinal canal, consequent upon partial twists and kinks in the bowel, which are prevented from untwisting themselves by adhesions which tie them to the parietal peritoneum.

Under these conditions the symptoms of obstruction are usually not constant, for if the bowels

Figure 1.

are in good order they are able to pass their contents comfortably through the partially obstructed coil. When, however, they become overloaded, or when, in consequence of neighboring inflammation, the intestinal peristalsis is interfered with, there may be produced all the symptoms of an acute stoppage. In the cases of this sort which I have seen, the seat of obstruction has been either in the ileum, close to its entrance into the cecum, or in the sigmoid flexure.

Has this experience been accidental, or is there a reason why these two portions of the intestinal tract should be more liable to this form of obstruction? A little consideration will, I think, convince us that this localization is not the result of accident. The other portions of the small intestine are so movable that they can shift about and adapt themselves to any coil which becomes fixed by adhesions. In the large intestine, on the other hand, its relatively fixed position prevents its being thrown into kinks, so that, even if it is fixed by adhesions, it keeps a more or less normal position. At both of the above-named points, however, we have a movable portion of the intestine running into a more fixed part — the ileum into the cecum, and the sigmoid flexure into the rectum. As we shall see presently, this relation of a movable to a fixed portion is favorable to the production of the form of obstruction about which we are speaking.

In studying the mechanism of this form of obstruction let us first consider that taking place in the ileocecal region. At the ileocecal valve the ileum — which up to that point has had the greatest mobility — passes into the cecum, which is relatively fixed. The appendix, close by, makes this region peculiarly liable to inflammation and consequent adhesions. If now, during an attack of appendicitis the ileum sags downward or across the lower end of the cecum, it is liable to become attached to the parietal peritoneum in such a way as to make it form a sharp turn at its entrance into the large intestine. When an operation is undertaken on a case of this sort, the cecum is found tied down by adhesions so that it cannot be readily drawn up into the wound. On following the lineæ tendineæ downwards they are seen to disappear beneath a coil of small intestine anchored by adhesions over the lower end of the cecum. This coil is firmly adherent to the parietes along the pelvic brim outside of the cecum, and must often be dissected with the knife from these attachments before it can be freed and pushed towards the middle line. When it has been thus freed it is seen to be the lower portion of the ileum, and the appendix is usually found buried beneath it or curled back under the head of the cecum. I have met with several such cases; and, by operation for the removal of the appendix between attacks, have had the opportunity of verifying the above-described pathological condition.

A review of the clinical history in several of the cases thus observed has convinced me that this malposition of the ileum produces a decided obstruction, and distinctly modifies the symptoms in inflammatory attacks in this region.

Such a buried appendix is subject to exacerbations of inflammation of a subacute type, and during such an attack, if the evidences of obstruction, namely, the obstipation and pain, are quite out of proportion to the fever and other signs of inflammation, we are justified in suspecting that a mechanical obstruction is superadded to the appendicitis. This suspicion will be confirmed if a mild but thorough catharsis gives immediate relief.

It might be thought that the separation of adhesions and the restoration of the ileum to a more normal position would be sufficient for the relief of such cases. This is, however, not the case. In the year 1894 I operated on two patients having this condition. In neither of them could the appendix be found by a search which, at the time, seemed to me thorough. I therefore contented myself with a thorough separation of adhesions. Both of these patients experienced some temporary relief from the operation, but presently the attacks returned. One of them was lost sight of; but upon the other I did a second operation, and found that the adhesions had re-formed. After again separating them, the appendix was sought by a difficult dissection, and found buried in cicatricial tissue beneath the cecum. It was removed, and this operation was followed by complete relief. From that time I have never failed to find and remove the appendix in these interval operations, and have never seen any recurrence of adhesions to a sufficient degree to cause obstructive symptoms.

Since this paper was read I have met with one other case of adhesion about the cecum, probably dependent upon appendicitis, which presented unusual features and is worthy of record here.

Case A. E. P. D., a man of thirty, entered the Massachusetts General Hospital March 3, 1901, with an acute attack of appendicitis. He had had but one previous attack that he could remember, and this occurred last Christmas evening, when he had severe vomiting and pain in the abdomen, but was up and at work the next day. From that time he was subject to slight pains in the abdomen till the night before entrance, when he was again seized with pain and vomiting, which persisted up to the time when I saw him.

As soon as preparations could be made, he was operated on. The appendix was found to be large, tense and congested, with flakes of lymph surrounding it. It was quickly removed, and then the following further condition was found: About midway between the base of the appendix and the hepatic flexure the ascending colon was bound to the lateral wall of the abdomen by a firm, well-organized adhesion. The colon beyond this point was of full size and contained gas, the small intestine was congested and moderately distended, while the cecum was totally collapsed and pale in color. As the adhesion was separated the colon gradually expanded and rolled towards the middle line, and the cecum filled and assumed its normal proportions. When the separation was fully effected, it was seen that the upper part of the adhesion had been attached to the intestinal wall on the inner side of the colon not far from the ileocecal valve. Thus it was plain that by the gradual pull of the adhesion the intestine had been rolled out until the inner wall — that is, the wall which should have looked inward towards the middle line of the body — was held tightly against the lateral wall of the abdomen in the right loin.

To explain this curious condition of an empty cecum lying between a distended small intestine and a full ascending colon, we must conclude that the band of adhesion, besides encircling and closing the large intestine, also so pulled upon the ileocecal valve as to obstruct the passage through it as well. The insertion of the adhesion close to that valve would make this supposition seem the probable explanation. The exact manner in which this obstruction was brought about could only have been determined by opening the caput coli before cutting the adhesion. This naturally was not thought of. After a complete division of the adhesion the abdomen was tightly closed, and the patient made a quick and almost a febrile convalescence. The speedy occurrence of free and full evacuations of the bowels showed how entirely the obstruction was relieved.

This is one of the cases which shows how a mechanical obstruction, which has not before amounted to a complete occlusion of the bowel,

Figure 2.

may lead to a total stoppage, when an inflammatory or other condition causes an undue distention of the intestines in its neighborhood.

ADHESIONS OF THE SIGMOID FLEXURE.

On the opposite side of the abdomen the sigmoid flexure again presents a movable portion of the intestine entering below into a more fixed part. When the mesentery of the sigmoid is long this portion of the gut readily sags down into the pelvis, and, if an inflamed condition of the peritoneum supervenes, may readily become attached in that region. When this happens a sharp bend is formed at the junction of the sigmoid flexure with the rectum.

The writer has met with three cases in the past eighteen months in which such a malposition of the sigmoid has caused serious obstruction. Two of these patients were elderly men, and the third was a woman still young. The first case I will report in some detail, on account of special points of clinical interest.

CASE I. G. A. L., a spare man, fifty-four years of age, was seen on December 8, 1899, in consultation with Dr. H. W. Boutwell of Manchester, N. H., when the following history was obtained: In the previous April, without apparent cause, Mr. L. had a severe attack of abdominal pain, accompanied by obstipation. He was confined to the bed for several days, and during that time there was great sensitiveness to pressure in the left iliac region. Following this experience he had, within a short time, two similar attacks of less severity. He was then pretty well during the summer, but in September he had a fourth attack, ushered in this time by a chill. In addition to the obstipation, he now had also difficulty in urinating, not, however, amounting to a complete retention. On December 1st he had still

Figure 3.

another attack, with retention requiring the use of the catheter. Following this he had a constant uncomfortable feeling of desire for urination, and it was very difficult, even with laxatives, to keep the bowels open.

Examination of the urine showed it to be of good specific gravity (1.018), acid, with a slight trace of albumin, and a small sediment consisting of pus, large round and small caudate cells, with neither crystals nor casts. Nothing could be felt in the abdomen beyond a slight, even doubtful, sense of resistance in the left iliac region, which was a little sensitive to pressure. The examination of the rectum revealed nothing abnormal. The prostate was not large. A sound (No. 26 French) passed easily through the urethra, but was grasped rather snugly by the constrictor urethræ muscle. The diagnosis of some partially obstructive condition of the sigmoid flexure was made; but neither the nature of this obstruction nor the reason for the implication of the bladder could be made out.

Mr. L. came to Boston for further study of his case. His bowels were kept open with compound licorice powder and injections, but there was no improvement in his condition; and it was found that the injections always caused great pain throughout the bowels, apparently due to exaggerated peristalsis. Without an injection he was unable to have any movement at all. It was now noticed also that he had great sensitiveness over the base of the bladder.

The persistence of the condition of partial obstruction, and the very great discomfort it involved, seemed to demand an exploratory operation; and Dr. F. C. Shattuck, who now saw the patient, coinciding with this view, this course was decided upon.

On December 27th an incision was made in the median line. The upper part of the sigmoid flexure was adherent to the top of the bladder and to the neighboring portion of the pelvic wall on the left by firm adhesions. When these were separated so that this part of the sigmoid flexure could be lifted up, it was found that a very considerable portion of the flexure below this was carried down into the pelvis and held there by this fixation of its upper part. Searching for the cause which led to this condition, the appendix was found tied up and surrounded by adhesions, some of them more recent than that which existed around the sigmoid flexure. The appendix itself was very small, not larger than that of a new-born child, and its base was tightly constricted by fibrous bands around it. The appendix was removed, and further search failed to show any additional trouble.

The patient made a good recovery, and was relieved of the obstructive symptoms which had been so troublesome. Some months later he had a slight recurrence of discomfort in the region of the sigmoid flexure. This soon passed away, however, and was no more than might have been expected in a sigmoid flexure so long and lax as this was known to be.

CASE II. J. W. T., aged sixty-five. This patient at the age of thirteen had dysentery, which confined him to bed for several weeks. The following year he had another attack, which lasted two months. Off and on during the next thirty years he had mild attacks of diarrhea associated with slime and blood in the stools. During the past six years he has had no such symptoms. He was operated upon for fistula ani thirty-five years ago, and since that time has had three other operations for recurrent fistulæ. Thirty years ago he began to be troubled with tympanites, which he controlled by mild laxatives. This reappeared at intervals, however, up to the present time. Four months ago he had an attack of abdominal pain located in the left iliac region.

This pain was relieved by a free action of the bowels, but during the attack it was severe enough to cause vomiting. Since that time he has had four such attacks, each one being associated with vomiting, which gave great relief. During the attack pressure in the left iliac region would give relief, and there was no tenderness. In all the above attacks large enemata of water were used (three quarts being thrown in), and when the whole enema was in the bowels relief came at once. When the enemata came away they usually brought considerable fecal matter with them. On the 19th of May, 1900, in the morning, he had another of these severe attacks of pain. This time the pain was not relieved by enemata, though several were given. Opiates controlled the pain but partially.

I saw him after this condition had persisted for three days. The obstipation was complete.

Figure 4.

Operation was advised and at once accepted. The incision was made a little outside of the left linea semilunaris. The sigmoid flexure was found attached to the parietal pelvic peritoneum, exactly as in the last case, only the adhesion did not extend on to the bladder wall. No sign of inflammation about the appendix was found in this case. The past history of dysenteric symptoms suggested the probability that the adhesions were due to inflammation about the descending colon and sigmoid. This adhesion was separated, and the operation was followed by complete relief and a rapid convalescence.

Case III. A woman of thirty, who had borne children and had had much pelvic distress, with a strong tendency to retroversion and prolapse of the uterus, had a ventral fixation done for the remedy of this condition. At this operation the sigmoid flexure was found tied down to the pelvic brim, much in the manner described in the other two cases. The Fallopian tube lay close beneath the adherent sigmoid and was slightly attached to it, indicating the probability that the inflammation which led to the adhesions was a mild grade of salpingitis. A subsequent inquiry elicited the fact that serious and obstinate constipation had troubled her for a long time, and that often the bowels resisted in the most obdurate manner all efforts to bring about a movement.

The form of obstruction in all of these cases was intermittent and incomplete; and in all of them, except Case A, the condition found had the same characteristic relation of a movable portion of the intestine twisted and adherent in a false position just at its entrance into a fixed part of the bowel.

The observations are too few, perhaps, to establish any rule, but their similarity is so striking as to fix the attention and to stimulate further study.

DESCRIPTION OF CUTS.

Figure 1 represents diagrammatically the condition found by the author in a number of cases of chronic appendicitis. The lower end of the ileum is drawn across the lower end of the cecum, covering the appendix.

Figure 2 represents the adhesions of the sigmoid flexure found in Case I. The fingers are represented as pressing down the top of the bladder, to which the sigmoid flexure is attached. The adhesions run along the brim of the pelvis, well out on the side of the abdominal cavity.

Figure 3 represents the adhesion in Case A before it was separated, and Figure 4 represents the same after the appendix was removed and the adhesion dissected off. The rough line crossing the cecum represents approximately the site of the attachment of the adhesion.

CATHARSIS IN ABDOMINAL SURGERY.

BY L. R. G. CRANDON, M.D., BOSTON.

The comparative effects of different cathartics and enemata, before and after operation, in surgical cases where the abdomen is the part of the body affected, is a study, the practical importance of which no one will question. I give the results of observations made during my service as house officer at the Boston City Hospital, and only regret the study is not a more exhaustive one. All the cases here considered were under the care of Drs. Gavin, Burrell and Monks, and are reported with their kind permission.

As in every clinical experience, so in this one, it is impossible to put a check on results to make conclusions absolute. Conditions cannot be controlled beyond a certain measure, and one is continually hampered by the personal factor of the patient. A record of facts, then, and a reasonable interpretation is all one can hope to give.

It has been proved by a number of studies in normal intestine and by use of purgatives, that peristalsis is almost entirely a reflex action. Direct experimentation as to how far up in the small intestine a wave may be started reflexly by stimulation of the large intestine alone has apparently not been done. The lower half of the ileum has been determined to be the part where the intestinal contents move fastest.[1] It has been found that the vagus nerve, when stimulated reflexly or directly, increases peristalsis, and that moderate stimulation of the splanchnic nerve decreases it. Any decrease, then, in the normal activity of the nerves and nerve centers must result in constipation.

It has been shown by experiments also that the circulation of the blood through the intestines greatly influences peristalsis, and disorders in the blood supply readily bring on intestinal disorder.[2] "Hepatic torpor," so called, or a diminished flow of bile, has its constipating effect partly in diminishing an irritant which may stimulate peristalsis, partly in diminishing a saponifying agent. Since the work of Pfaff and Balch our cholagogues have been apparently reduced to one; namely, bile, human or bovine.[3]

The most important conditions, then, under which peristalsis may take place along the small intestine are (1) a relatively healthy condition of the whole thickness of the intestinal wall, and (2) the integrity of the reflex arc. In surgical cases the wholeness and irritability of the reflex arc are similar to that of the whole nervous system in the given case, and therefore depend only on the general condition of the patient, and not on the local surgical lesion. The first requirement of peristalsis — that is, the soundness of the intestinal wall — is the more important one, and this study was therefore directed toward the relation between the various forms of local stimulation and the condition of the part stimulated; namely, the gut. It was directed toward the best means of keeping the alimentary contents moving, in each case having in mind, however, a picture of the local condition of both large and small intestine. The object was to obtain the advantages of drainage and depletion which follow catharsis, and at the same time to obtain rest for the parts affected, the least loss of strength and the greatest comfort for the patient.

It may be urged that the comfort of the patient is a small consideration compared with real profit to him that may be incompatible with such comfort; but on further thought, the experience of anyone dealing with acute surgical conditions in the abdomen will tell him that griping pain from cathartics, with its consequent restlessness and loss of sleep, may be just enough in some cases to turn the patient back, to prevent him from starting on that reaction of rest so essential after surgical procedures.

In the series which I wish to present there are 179 abdominal or pelvic cases, which are divided as follows:

	Total.	Lived.	Died.
Peritoneal and pelvic inflammations and ovarian cysts	148	109	39
Tuberculosis	8	8	0
Malignant disease	2	0	2
Obstruction (mechanical)	21	14	7
	179	131	48

There are two principal ways for artificially inducing a movement of the bowels in a patient sick in bed; (1) by drugs by mouth (either in one large dose or in many small doses), and (2) by enemata. The cases in this series are accordingly divided into several classes, each of which, as will be seen, has its special bearing on the question as to the best means of moving the bowels:

(*A*) Inflammatory conditions of the abdomen before operation.

(*B*) Diseases of the female pelvis — outside the intestinal tract — before operation.

(*C*) All abdominal and pelvic affections after operation.

(*A*) In the first division come acute and recurrent appendicitis, and general peritonitis from perforation of the gut. In a large proportion of these cases before they were brought to the hospital the old rule of Dr. Holmes had been followed. This rule was to "give a cathartic, then go home and read up the case." For example, in 70 cases of appendicitis, 47 had had Epsom salts and 14 some other drug, the compound cathartic pill and calomel being the favorites. Over half of these had perforation of the appendix. Cases of this sort are common. I give two as illustrations.

CASE I. N. S., female, twenty years old. Four days before admission there appeared the first onset of general abdominal pain, nausea and fever. The pain soon became fixed in the right iliac region. There had been no movement for thirty-six hours before the onset. There was some spasm, no tumor. She had then been given calomel, one-half grain every hour for six doses. At the end of twelve hours she had a sudden griping, ripping pain in the appendix region, with considerable relief in half an hour, followed by a loose movement. Examination on admission shows a definite right iliac mass and considerable general spasm. Operation fifteen hours later reveals abscess from perforation of appendix; recovery.

CASE II. F. W., male, thirteen years old, third day of second attack. Forty-eight hours before admission he was given about an ounce of Epsom salts, with a good movement soon after. Examination on admission shows distended spasmodic abdomen, general tenderness, most intense in the right iliac fossa. Operation discovers the proximal half only of a gangrenous appendix, free fluid and feces in the peritoneal cavity — practically no adhesions; fatal result.

One cannot say in cases of this class that perforation is caused by active catharsis, for it may

[1] Sabbatani and Fasola; Arch. Ital. de Biologie, 1900, xxxiv, ii, 186.
[2] Hare: Practical Therapeutics.
[3] Journal Experimental Medicine, 1897, ii, 49.

be that increased movements of cecal contents free the outlet of an obstructed and distended appendix, and so prevent rupture. One may fairly say, however, that in many instances after laxatives by the mouth, symptoms are aggravated. This exacerbation of symptoms may be due to the increased peristalsis causing strain on newly formed adhesions in the iliac fossa, and consequent extension of inflammation. Movements of the wall of the small gut are particularly undesirable at this time. Peristalsis has been inhibited by the neighboring inflammation as a protective measure. Or, the aggravation of symptoms following a cathartic, if not due to the stirring up of an inflamed part, may be caused by increased tension in the appendix or rupture of it. To pour the accumulation of twenty feet of small intestine into the cecum must raise the tension in that organ, especially if it be already distended with feces or gas. All this may be avoided, and the appendix drained if possible at the same time, by emptying the large gut from below by an enema. The liquid contents of the small intestine may then come down naturally, when peristalsis can no longer do harm.

(*B*) In the second class are included pelvic diseases before operation; that is, cases of pelvic peritonitis through tubal infection, salpingitis, ovaritis and acute endometritis. There are 44 in the list. Most of these cases had had cathartics by mouth before coming to the hospital, and all had an enema on admission. It was only rarely that symptoms did not abate in twelve hours; there were free movements, an appreciable drop in temperature, and a disappearance of pain, spasm and tenderness. Here, then, the alimentary tract being so little affected, we are at liberty to empty the large intestine by enema, and at the same time to empty the upper bowel by drugs given by the mouth, thus getting the benefits of depletion and drainage by increased peristalsis in the upper part of the intestinal tract.

When the uterus, or tubes, or pelvic tumors have been removed, that is to say, in noninflammatory pelvic cases, it is unquestionably better, for fear of mechanically disturbing the adjacent wounds, not to distend the rectum with enemata, but rather to induce peristalsis from above. A small oil enema, however, in these cases prevents straining.

(*C*) It is the third class, namely, all abdominal cases after operation, upon which most interest and importance hang. Amongst these are included 132 celiotomies, 10 of which are for disease of the internal female genitals. In about one-fourth, or 30 cases, calomel was given after operation in two ways: either one-tenth grain every hour to 10 or 20 doses, immediately after recovery from the anesthetic, or one-half grain every three hours to 5 doses at the end of the second day. Of the 30, six complained of "griping cramp-like pain," 5 of these having had the larger and less frequent doses; 3 had movements as result of small doses, 12 as result of the larger doses; 15 had no movements; 18 had abdominal discomfort described as "rumbling," "feeling blown-up," "all-gone feeling," etc. Two had sore mouths (in these cases powdered calomel was placed upon the tongue, but no water was allowed on account of persistent vomiting, the patient being obliged to swallow the calomel as best he might with the help of saliva). Twenty-seven had dirty, bad-tasting tongue, with consequent aggravation of thirst. In only one case did it seem that there might be a connection suggested between free use of calomel and an untoward result.

Case III. Male, fifty-four years old; subacute appendicitis; operated; no pus; one-tenth grain calomel every hour to 20 doses; after thirty hours a profuse diarrhea started and persisted in spite of most strenuous therapeutic efforts, till his death at the end of four days. No general peritonitis.

In 51 cases after operation absolutely no cathartic was given by mouth till at least ten days after operation, and in many not till late in the third week. The bowels were moved solely by enemata. Seldom earlier than twenty-four hours after operation, but usually then, an enema was given through a No. 30 French soft rubber catheter, passed along the finger high into the rectum and into the sigmoid, if possible. The enema was made up of:

℞

Epsom salts (50% sol.).	
Turpentine.	
Glycerine,	*aa* ℥ *ij*.
Water,	℥ *vj*.

This enema, which is in constant use in the hospital, is held as long as possible by the patient, and usually produces a good movement of soft feces and gas, with no tenesmus. The sacrum and buttocks should be well oiled before this enema, to protect the skin from blistering, if it gets wet from the turpentine. The enema is repeated, as a rule, possibly three or four times on consecutive days, and after that movements are readily induced by an enema of suds and glycerine — a pint to two ounces. In the turpentine enema the proportions above given seem to produce a maximum result with minimum discomfort.

The remaining 51 cases were treated usually by enemata alone, occasionally combined with calomel, a saline, or with other cathartics, and present varying results, the patient's comfort being, on the whole, proportionate to the number of movements by enema alone.

Figures as to the effect on temperature of either method of inducing a movement, from above or below, can have no value, because so many elements serve to determine each patient's condition at a given time. It may be said, however, that a dejection by enema will lower a temperature $\frac{1}{2}°$ to 1° within two hours, and coincidently produce subjective relief where drugs by mouth take three to twelve hours.

In the entire list given is one case of general peritonitis that recovered, and there are many, of course, where there was beginning inflammatory

reaction, as shown by the general spasm before operation, and the fibrinous flakes discovered during it. In all these after operation the bowel was emptied by stimulation from below; that is, by enemata, rather than by irritation of the many feet of small intestine above. There are 5 instances of appendix so thoroughly gangrenous that there was no stump to be tied off or invaginated. In these the inflamed bowel was kept empty by enemata, and yet given surgical rest. In none of these did a fecal fistula appear.

Another class of cases to which much of this reasoning applies are those which are operated for radical cure of inguinal hernia. An effective enema avoids straining at stool, and prevents the pull on the newly sutured muscles. In no case was there apparently developed a dependence on enemata after convalescence. In the third week cascara was given occasionally, and later natural movements were soon established.

This method — that is, using enemata alone after operation and before operation in all cases where the alimentary tract is involved — combines the best in both the so-called medical and surgical treatment: peristalsis is checked, quiet for the diseased part is obtained, and drainage by the shortest way is assured. In the line of treatment by enemata the fecal receptacle — the large intestine — is kept empty; distention with gas, most of which is formed in the colon, is never considerable; inspissated rectal contents cannot remain, and so block the exit of feces or gas from above; straining at stool, with consequent pull on the abdominal wound or new adhesions, never occurs; the rectal tube for the further relief of gas, if necessary, does not get plugged, and such nourishment as the stomach and intestine have been induced to accept is not unduly hurried along at a time when the patient needs all the strength he possesses.

The conclusions which seem to me warranted are that: (1) In acute pelvic peritonitis both enemata and drugs by mouth should be used to produce catharsis before operation; drugs by mouth and oil enemata after operation. (2) In all acute inflammatory conditions of the abdomen where the alimentary tract is involved, the bowels should be moved by enemata alone, before and after operation, the enema of salts, turpentine and glycerine being the best.

Clinical Department.

A CASE OF MEASLES COMPLICATED BY APPENDICITIS.[1]

BY HAROLD WILLIAMS, M.D., BOSTON.

M. P., aged twelve years, first complained of feeling ill on March 31st. He was never a strong boy, and had frequently suffered from attacks of gastro-intestinal disturbance. He had had measles some years previous. The symptoms of present attack consisted of nausea and general malaise. Temperature 100°. He was put to bed and dieted.

April 1st. He was less comfortable, though no new symptoms appeared. Temperature 101°.

April 2d. Patient complained of slight sore throat and vomited once. Temperature 102°.

April 3d, I first saw him. Patient not so comfortable as upon days previous. Temperature 103.4°. Had vomited once or twice; complained of abdominal pain; cough, weak eyes and sore throat. Inspection: Conjunctivæ slightly injected; mouth red, with striking congestion of alveolar processes; congested appearance of posterior pharynx and a catarrhal inflammation of right tonsil to which uvula was adherent. Koplic sign not present. Careful examination of the abdomen showed some tenderness in different places; always fleeting and never localized.

April 4th. Well marked eruption of measles on face and behind ears. Eruption confluent; conjunctivitis more marked; cough still slight; abdominal symptoms as before. Temperature 104°.

April 5th. Eruption well marked and extending over neck and trunk. Temperature 104.4°. Early in the morning patient had complained of pain in right side. This pain had steadily increased in severity. At 10 A.M., when I saw him, it was exactly located at a point an inch above Ponpart's ligament; it was increased on the slightest pressure, and the locality was indicated by patient with one finger. There was neither dullness nor induration. The diagnosis of an acute inflammation of the appendix was made. Dr. Arthur T. Cabot was called, and the case was placed in his charge. It was also thought advisable that Dr. J. H. McCollom should give us the benefit of his wide experience in measles, the association of which disease with a fulminating appendicitis in a boy of delicate physique seemed a matter of some gravity. Dr. Cabot, in view of the probable rapidly advancing process, decided upon immediate operation, in which decision Dr. McCollom and I concurred. The operation was performed by Dr. Cabot two hours later, with the assistance of Dr. Hugh Cabot.

April 6th. Temperature fell to 99° during night, and remained at this point throughout a remarkably satisfactory convalescence.

Pathological examination of the appendix by Professor Mallory is as follows:

April 6, 1901. Appendix; gross examination: Appendix 4.5 cm. long, varied from .6 - .8 cm. in diameter. Somewhat swollen in middle two-thirds. Serous coat injected, especially at tip; fresh fibrin adherent in places, forming irregular yellow areas. Mesentery injected. Split open nearly to tip; contains a fecal concretion size of small bean. Proximal end of mucosa swollen, lumen quite small and partly filled with creamy, tenacious, purulent material; beyond this is a definite enlargement of the lumen, in which the concretion closely fits; the mucosa here is dark red to greenish, and is evidently becoming gangrenous; beyond this dilatation the mucosa is thickened, and there is some mucopurulent secretion.

Anatomical diagnosis.— Acute appendicitis.

Microscopic examination of a longitudinal section shows an acute exudative process, most marked on the

[1] Read before the American Pediatric Association, Niagara Falls, May 29, 1901.

outer surface of the appendix. The mucosa is fairly well preserved, but is infiltrated in places with numerous polynuclear leucocytes.

The event proves, so far as we can judge from a single case, that the complicating presence of measles is not a contraindication for the operation of appendicitis under circumstances in which the highest surgical skill is obtainable. The combination of the two pathological processes is, so far as I know, a rare one.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D., AND PAUL THORNDIKE, M.D., BOSTON.

NON-OBSTRUCTIVE, POST-OPERATIVE ANURIA.

F. Tilden Brown[1] makes use in this article of a case in which anuria followed upon nephrectomy, to illustrate the subject of post-operative anuria in general, and does it in a pleasing way.

Death resulted from heart failure and renal suppression, and the causes of these conditions in this case are inquired into. The three probable factors concerned in them he states as (1) chloroform anesthesia; (2) compression of the kidney and vessels of its pedicle and subsequent hyperemia, produced by a long-continued pressure from the position of the body placed on its side over sand bags; (3) some essential vasomotor reflex started by ganglionic pressure, or through the renal plexus, from removing the fellow kidney, or a congestion incidental to an increased physiological demand. The remaining kidney showed at autopsy the following condition: Weight 6½ ounces; rather pale. Some congested stars on the surface; surface smooth. Glomeruli congested. Markings indistinct; pyramidal markings somewhat exaggerated. Pelvis slightly distended. Mucous membrane congested and shows petechial spots. The urine from this kidney had been tested and found of good quality and quantity at intervals of a month before the operation. Post mortem showed nothing beyond congestion.

The writer goes on to give the grounds for assuming a reflex vasomotor paralysis and consequent passive congestion as the cause of the renal suppression. The effect of posture of the patient is emphasized, and the probable ill effects from pressure on the kidney of the side opposite to that one operated on are noted; and the use of a double inclined plane with an interval opposite the kidney, which removes all pressure from it, is urged. Such a contrivance is illustrated in the article.

CONSERVATIVE OPERATIONS FOR RENAL RETENTION.

Christian Fenger[2] contributes a valuable contribution to the surgery of the ureter and of some of its most modern developments. It introduces some operations that will be new to the general surgeon and medical practitioner and, unhappily, some new and rather tortured nomenclature, to describe them.

Obstructions of the ureter and the choice of methods for their relief are discussed and illustrated by the reports of cases; cases of retention from calculus, and its removal by movable kidney and nephropexy, nephrotomy and drainage, and drainage by ureteral catheter from below, are omitted from consideration. The following cases are reported:

(1) Obstruction located in the kidney; namely, in the calyces or one branch of the ureter; partial cystonephrosis. This operation consists in the bisection of the kidney and division of the partition walls between the sacs and the pelvis, thus making a unilocular.

(2) Obstruction situated at the exit of the ureter from the renal pelvis. The condition found causing obstruction in cases of this kind has been a valve formation without stricture, due to unilateral dilatation of the pelvis and consequent oblique insertion of the ureter on the side of the dilated pelvis rather than at its lowest point, or else stricture of the ureter at its exit, with insertion at the lowest part of the pelvis or on the side higher up. The operations which have been applied to these conditions are to attack the obstruction through the pelvis or bisected kidney in case of the valve-like formation — transpelvic operation; or from without — extrapelvic operation. Finally, the distorted shape of the pelvis has been made the operation — "pyeloplication" and "capitonnage." These operations are described briefly. The two terms above quoted are spoken of as follows: "Pyeloplication,"— plastic operation on the renal pelvis (Israel) ("pelvioplication Albarran"). In lateral implantation, when the ureteral orifice is of normal caliber, the passage of urine would be free were the ureter inserted at the lowest part of the pelvis, or if the normal shape of the pelvis were re-established, which has been accomplished by the following operations on the pelvis: (a) Shortening the excess of the pelvic wall by folding it toward the lumen of the pelvis and uniting the folds by sutures; (b) excision of part of the wall of dilated pelvis and closure by sutures ("capitonnage Albarran").

(3) A case of obstruction below the renal pelvis relieved by an operation, to which the name "uretero-lysorthosis" is given.

The article ends with a series of conclusions, which include (1) the choice of operation; (2) the danger to life; (3) the effect of operation; and with a table of the operations done up to the present time.

A NEW METHOD TO EXPOSE THE SEMINAL VESICLES AND PROSTATE, FOR PURPOSES OF EXTIRPATION AND DRAINAGE (A PRELIMINARY REPORT).

Eugene Fuller,[3] M.D., New York, points out the defects and inadequacy of the hitherto employed methods of approach to the prostate and

[1] Annals of Surgery, March, 1901, p. 225.
[2] Chicago Annals of Surgery, April, 1901, p. 369.
[3] The Journal of the American Medical Association, May 4, 1901, p. 1228.

seminal vesicles for the purpose of radical operations upon them, and then goes on to describe his own plan of procedure, which is as follows: To render the parts easy of access and less movable during dissection than they are in other postures, the patient is placed as follows: The legs are flexed as for lithotomy, the body turned over on its face, the buttocks raised on one end of a Trendelenburg table with the thighs astride of the elevated part. This puts the perineal tissues on the stretch and affords the firmest and widest surface of them on which to operate. The bladder is emptied just prior to operation, but no catheter is left in during the succeeding steps. The rectum is filled by a tampon passed high up into it, in order to prevent its contents from reaching the field of operation. The incision is now made thus: As the surgeon is seated the patient's buttocks raised as described are directly opposite him; the incision consists of two somewhat oblique incisions, one on either side of the perineum, beginning on a level with the tip of the coccyx; and just inside the ischium the two lateral branches are carried forward longitudinally through the perineum, and are united by a transverse cut at their other ends, about three-quarters of an inch beyond the anterior margin of the anus. The longitudinal branches are extended into the deep tissues, and then the tranverse one also. The flap so formed is turned back, and the deep dissection completed through the space thus gained.

RESECTION OF THE EPIDIDYMIS AND ANASTOMOSIS OF THE DIVIDED TISSUES.

Scaduto[4] discusses the possibility of restoring the function of a testis in cases where it has been interfered with by disease or necessary operation. The work is based upon 14 operations, performed upon dogs, and the author was successful enough, in one case at least, to feel that further experimentation should be conducted on similar lines. His method was to make the resection and anastomosis, the technique of which he describes with some care, and then after several weeks to remove the testis and cord, inject the latter with hot, colored gelatine, and harden in alcohol. He then made microscopic sections to determine the patency of his operated area and its neighborhood.

TREATMENT OF TUBERCULAR EPIDIDYMITIS BY LIGATURE OF THE VAS DEFERENS.

Mauclaire[5] reports 18 observations upon the results of the treatment of tubercular epididymo-orchitis by ligature and section of the spermatic cord, and concludes: (1) Good results may be obtained when the tubercular area is not fistulous or suppurating; (2) in the suppurating cases the results are not good, because the process continued (in his cases) and invaded the tunica and other neighboring tissues.

A NEW METHOD OF PERFORMING PERINEAL PROSTATECTOMY.

P. J. Freyer[6] recommends the old Dittel incision with a preliminary perineal incision into the urethra as a substitute for the suprapubic cystotomy of Nicoll. That is to say, he removes the prostate by the perineal route through the Dittel incision; but instead of doing a preliminary suprapubic cystotomy, as Nicoll does in his operation, Freyer makes a preliminary perineal opening into the urethra and claims the following advantages in so doing:

(1) The preliminary urethrotomy permits the introduction of the finger into the bladder, which, with another finger in the rectum, enables the surgeon to define accurately the size, shape, density and extent of the growth without the performance of a suprapubic cystotomy.

(2) The finger can be hooked over the enlarged lateral lobe, and the latter pushed well into the ischiorectal wound, thus obviating the deep and dangerous dissection of Dittel.

(3) With the tumor pushed into the wound the capsule is easily incised, and the cutting forceps and scissors easily applied.

(4) The finger in the bladder warns the surgeon when the cutting instrument is approaching dangerously near that organ, so that the whole growth can be removed, except a thin layer for the support of the mucous membrane of the bladder and prostatic urethra, without opening the latter, thus avoiding infection of the wound and formation of a permanent fistula.

(5) The perineal drainage tube inserted into the urethral opening carries off the urine and prevents sepsis of the perineal wound.

AN IMPROVED METHOD FOR PERFORMING SUPRAPUBIC CYSTOTOMY.

C. L. Gibson[7] affirms that the improvement consists in adapting to the bladder the principle which underlies the so-called Kader operation for permanent gastric fistula. The writer hopes that the procedure will accomplish three things: (1) Effective bladder drainage without leakage; (2) rapid closure of the fistula when the drainage is discontinued; (3) the creation of a permanent sinus if desired, which should allow of permanent but periodical catheterization of the bladder, and in the intervals, owing to its valve action, prevent the escape of urine, and do away with the discomforts of wearing a tube or dressing.

THE URETERAL CATHETER A DEMEURE IN PREVENTIVE AND CURATIVE TREATMENT OF RENAL FISTULÆ.

Albarran's interesting paper was read at the Thirteenth International Medical Congress in Paris last summer, and is summarized in the *Annales des Maladies des Organes Genito-Urinaires*, 1900, page 799. The author describes how renal fistulæ which have refused to heal because of a more or less impermeable ureter can be made to heal by proper drainage through a ureteral catheter. He reports cures of two such cases in from fifteen to twenty days. He believes that such fistulæ may often be prevented by a similar use of the ureteral catheter at the time of operation.

[4] Am. des mal. des Organes genito-urinaires, March, 1901.
[5] Thirteen Congrès. Internat. de Med., Paris, 1900.

[7] Journal Cutaneous and Genito-Urinary Diseases, March, 1901.

DETERMINATION OF THE CONGEALING POINT OF THE BLOOD AND URINE IN ORDER TO ASCERTAIN THE FUNCTIONAL ACTIVITY OF THE KIDNEYS.

Kummel,[8] Von Korányi and others have demonstrated the fact that the congealing point of the blood in a physiological condition remains at about —56° C. The moment the kidneys cease to functionate properly the congealing point goes below —56° C. In all cases (tumors, pyelitis, pyonephrosis, tubercular kidneys, nephritis of various sorts, etc.) which the writer examined or operated, this proved true. The congealing point of urine may be made useful in a similar way, and the urine from each kidney may be tested separately in any case where one kidney is diseased and the other possibly not affected.

RADICAL TREATMENT FOR CURVATURE OF THE PENIS.

Fuller[9] describes an interesting operation for the cure of curvature of the penis (on erection), which exceptionally follows internal urethrotomy to such a degree as to prevent sexual intercourse. The operation consists in making a very long median perineal incision, and through it dividing the urethra in the bulbous region very obliquely and in such a manner that when the penis is bent back over the pubes a maximum amount of separation of the cut urethral ends is obtained. The penile cut end is then stitched in place to the surrounding tissues. The bladder end needs no fixation. A perineal drainage tube is tied in place for some time. In Fuller's case the result was good two years after the operation.

RARE AND INTERESTING CASES.

(1) A case of complete anuria of seven days' duration with no symptoms of uremia.[10]

(2) A case of complete retention of urine and *rupture* of the urethra in a case of gonorrhea without organic stricture of the urethra.[11]

(3) Another of the rare cases of torsion of the spermatic cord.[12] Diagnosis was verified by operation.

TWO NEW CYSTOSCOPIC INSTRUMENTS.[13]

(1) A modification of the original Nitze cystoscopic lithotrite and foreign body forceps. The instrument consists of a cystoscope, lying in and freely movable in the forceps. In the Nitze instrument the movable jaw moved toward the prism and so obstructed the field of vision. In this instrument the posterior jaw is fixed and fenestrated, and the anterior jaw is the movable one. This improvement leaves the visual field comparatively unobstructed.

(2) A cystoscopic foreign-body forceps. The cystoscope lies in a tubular canal on the posterior surface of the instrument, and is freely movable in it, though its mobility can be controlled by a screw. The forceps open laterally, leaving the field of vision clear.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

F. G. BALCH, M.D., SECRETARY.

REGULAR meeting, Wednesday, February 6, 1901, DR. J. C. MUNRO in the chair.

DR. J. B. BLAKE showed a case of

SARCOMA OF THE HUMERUS AND SCAPULA.

This patient came to the City Hospital in December, 1897. At that time she was thirty-one years of age, and the history briefly was that of a fall on the *right* side, a year previously, and pain and disability of the *left* shoulder. This was followed by increasing limitation of motion, and within a week or two before entrance she found for the first time a small tumor occupying the position of the coracoid process. She was in good general condition, the arm limited very considerably in its motion, and presented near the tip of the left coracoid process a tumor not distinctly fluctuating, and distinctly not pulsating. Diagnosis was reserved, but sarcoma was considered probable.

Operation.— A curved incision was made, and separating the pectoralis major and the deltoid a rounded tumor was found occupying the entire end of the coracoid process; that is to say, the pectoralis minor and coracobrachialis went directly into it. The brachial plexus and axillary artery were laid bare, and at that time the tumor began to break under the fingers and to bleed very profusely. Clinically it had all the aspects of a sarcoma of very hemorrhagic type. It broke away like a rotten sponge. It bled so rapidly that at one time it was feared that we might lose the patient from hemorrhage. The tumor, including the tip of the coracoid, head of the humerus and part of the glenoid cavity, was removed and a mass of sharp spicules of bone was left. So far as I could see the tumor mass was entirely removed and the place occupied by it was packed firmly with gauze. The patient was taken off the table in fair condition.

About two weeks after that the Coley treatment was started, commencing with a half-minim dose, increasing gradually, and continued while she remained in the hospital. She went out in July, the wound being practically healed, except a small sinus.

She came back to the Surgical Out-patient Department several times until December, 1898. She is now in a household of five, in which she is the only servant. The motions of the arm are entirely free, except extension upward, which is slightly limited.

Six months after the original operation Dr. Cushing dissected out two or three small glands just above the clavicle. Pathological examination showed them to be chronic inflammatory. The pathological report signed by Dr. Mallory and Dr. Bottomly showed the original tumor to be giant cell sarcoma.

During the operation, in the hurry of the dissection I nicked the musculo-cutaneous nerve. She never had any symptoms following it. There are no glands in the axilla. Her general health is about as good as when she entered the hospital.

DR. A. T. CABOT read a paper entitled

SOME FORMS OF INTESTINAL OBSTRUCTION DUE TO ADHESIONS.[1]

DR. MUMFORD: In his very suggestive paper Dr. Cabot has illuminated one corner of a wide field most important to all surgeons operating inside the abdomen. That a great number of obscure symptoms — pain, dragging, tenderness, constipation, dyspepsia, renal incompetence, etc.— are not infrequently due to adhesions, the result of inflammatory processes in or around the various abdominal viscera, is undoubted. The phenomena grouped under the general term "enteroptosis" play an important part.

Some years ago I reported a case of "stercoral ulcer," a process which I then thought, and still think, to be in a greater or less degree more common than is generally supposed. Long-standing fecal accumulations with resulting erosion, localized necrosis and adhesive peritoneal inflammation, such as I described in the above-cited case, are the undoubted forerunners of adhesions. The stomach, gall bladder, bladder, uterine annexa and other hollow viscuses may be the seat of these processes, as well as the intestinal tract; giving rise, in their appropriate locations, to such adhesions as Dr. Cabot has described; and in many cases, of course, with the subsidence of the primary process, no gross evidence remains to indicate its seat.

With advancing age, numerous pregnancies and great loss of flesh, such inflammatory adhesions may aid in establishing and rendering permanent those conditions of enteroptosis with which we are familiar. The two conditions may then act and react upon each other *ad infinitum*.

As to the two examples of intestinal adhesions which Dr. Cabot has described, I confess that they, in their immediate and serious sequelæ, had not forcibly occurred to me before. Perhaps the most common seat of adhesions within the abdomen is about the caput coli, causing most frequently, doubtless, a gluing down of the coils of the ileum. But just how this might cause a constipation, or even an obstipation, had never occurred to me until I saw Dr. Cabot's instructive diagram. I remember being present at the first operation on the patient whose case he described, and it seemed to me then that the matting down of the ileum was quite enough to cause serious pain and disturbance. The long course of the disease in that case rendered most plausible Dr. Cabot's supposition that the appendix had been destroyed by natural processes.

As for the interesting sigmoid cases mentioned by Dr. Cabot, I have no personal experience of their like; but after his instructive statements I have no doubt that I shall suspect and discover them in my future work.

[1] See page 635 of the Journal.

Undoubtedly freeing of the adhesions is all that we are justified in doing, and in most cases that is sufficient. Sometimes denuded surfaces may be turned in with a few Lembert stitches. This is rarely necessary; and we must suppose, in view of the subsequent history of these cases, either that no new adhesions form, or that if formed they are so placed as not to impair function.

Dr. Cabot's cases are certainly an interesting and important contribution to our knowledge of this subject.

DR. LUND: I was very much interested in the picture. I did not hear the description of it, as I came in late. I have operated for obstinate constipation following operation for removal of the appendix, in which the small bowel was found drawn across the front of the cecum and adherent to the under side of the abdominal wall, so that the patient said the scar drew in when the bowels moved. There were one or two broad adhesions and two bands leading upward. Those were separated; and where the broad adhesions were separated I took one or two catgut ligatures to close the surfaces. Soon after the operation she went to Ireland. She was entirely relieved of her pain.

DR. GARCEAU: I have had one case exactly like the ones Dr. Cabot has described. It occurred in a young girl in whom I suspected tubercular peritonitis. I operated and found the abdomen full of adhesions, and this condition was found. The adhesions were so general that I can very readily understand how they could travel across the abdomen and fix the sigmoid flexure in the way that Dr. Cabot has described.

DR. MUNRO: This seems to me one of the most important subjects we have had brought out for a good while. I have been in the position a number of times of having a family doctor protest against operation for adhesions, on the basis that they would be just as bad after operation as before. It is a comfort to hear that it is not so, and to have Dr. Cabot's experience as a basis. Not long ago one of our orderlies at the hospital came with a story of repeated mild attacks such as Dr. Cabot has described. At operation we found that the appendix itself had atrophied to a longitudinal band, except for one-fourth of an inch at the base; there were adhesions which were broken up; and now, after some months, there has been no return of the old trouble. I never have seen the adhesions of the sigmoid described by Dr. Cabot, but I can easily believe it would cause consternation in the abdomen.

DR. CABOT said that in trying to limit the discussion to these particular points he had left out a great deal that could be said about abdominal adhesions. One of the most interesting and curious facts is the way adhesions disappear. During an operation for some intra-abdominal condition everything may be found matted together, and by an operation on the same patient later it will be found that there are almost no adhesions left. At other times the adhesions persist in certain localities, as we have seen, and sometimes cause much trouble. Of adhesions about the stomach

much might be said. The stomach is an organ that is constantly filling and emptying, altering its size and weight more than any other part of the intestinal tract. Close by we have the transverse colon, which is again a part of the intestine which constantly alters its size and is often filled with heavy contents. Inflammations are common in this upper part of the abdomen, originating in the gall bladder, the biliary ducts, or more rarely in the stomach or duodenum. As a result of such inflammation these heavy viscera, the stomach and transverse colon, are apt to become adherent to the gall bladder and the under surface of the liver, and to constantly pull on these very sensitive parts. If these adhesions cause a stoppage of the biliary ducts, or confine the pylorus or duodenum so as to interfere with the passage of ingesta, we may have symptoms distinctive of such obstruction. In many cases, however, where no such mechanical obstruction is brought about, the constant drag on the under surface of the liver and the delicate parts thereabouts keeps the patient in uneasy consciousness of discomfort in the epigastrium. Such a condition in a neurasthenic patient is favorable to the production of stomach crises, manifesting themselves either by pain or vomiting, or both.

Dr. Munro: I would briefly report a case, although Dr. Blake really knows more about it than I do. A young undertaker, thirty-three years of age, came to the hospital in 1897. At that time he had a mass of glands in both triangles of the neck down to the clavicle, starting under the second or third rib about two years before and steadily increasing upwards. He came in for operation for pressure against the trachea, and I removed the glands down to the clavicle; but below that it was useless to go, as the sheath of the vessels was involved and the growth extended downwards indefinitely. A violent staphylococcus infection followed operation, but he left the hospital in the course of a few weeks, relieved. After that there was recurrence, and his mother or grandmother rubbed on goose oil or some family remedy, with relief temporarily. He then went to the Massachusettts General Hospital, but the growth was so far advanced that all the surgeons who examined him refused to operate. He then adopted his own remedy,—rum, and since 1898 he has been practically full of rum all the time. Within the last month he came to the hospital with what we call an "edge" on, but the tumors had practically disappeared. Meanwhile Dr. Blake, I think, has dissected out the axillæ, which were occupied by sarcoma.

Dr. Blake: I met this patient on the street, and he had on a No. 18 collar and looked as if he had stuffed his shirt with something. That was just before his mother recommended goose oil or St. Jacob's oil. The next time I saw him he was wearing a No. 15½ collar. In the spring of last year I dissected out the axillary glands. They ran well back under the lassissimus dorsi. When he came back he had one small gland in the middle of the axilla and one or two small ones near the inner part of the left clavicle. While treated in the out-patient department he had an eruption which for a time suggested syphilis. Dr. Dwight looked him over carefully, but could not be satisfied he ever had syphilitic infection. He looks to me about as well as two years ago.

Dr. Munro: I had an apparent cure from erysipelas in a Russian Jew, fourteen years old, who entered the medical side with universal lymphosarcoma. One evening he began to choke up and was transferred to the surgical service at once. I expected to find a deep cervical abscess, but instead found soft broken-down glands without pus, very much swollen, and evidently in the beginning of a streptococcus infection, because almost at once a severe erysipelas developed and his universal lymphosarcoma disappeared. He went out apparently well, but in a few months came back with a recurrence and died.

Dr. Cabot said that in the cases reported were three different kinds of sarcoma, which had very different tendencies to recurrence. The last case was probably lymphosarcoma, and he recalled one case in which an enormous lymphosarcoma in the neck of a small boy disappeared under the use of stimulants with good food. He had known of other cases in which lymphosarcomata had disappeared, apparently as the result of the exhibition of arsenic.

In Dr. Blake's case the tumor was a giant-cell sarcoma, which is a variety unlikely to recur after a thorough removal. It is not possible, therefore, to regard this case as furnishing any evidence of the efficiency of the streptococcus serum.

Among the sarcomata we have tumors of very widely different characteristics. Some of them are most malignant, and some have but little malignancy. We need to know more about the classification of sarcomas before we can draw conclusions from their behavior with this or that method of treatment.

Dr. Blake: The patient with the sarcoma of the neck went to New York and saw Dr. Coley, who said while he could promise him nothing, he was willing to treat him. The man, however, had not the requisite means, and returned without treatment.

I recall a case of what I supposed to be a wen, of thirty years' standing, removed in the surgical out-patient department from the head of an old woman, which the pathologist reported to be sarcoma.

Dr. Painter: I recall the case of a homeopathic physician from a neighboring city who was advised to try the hot-air treatment for a large tumor of the thigh, and came to consult us for that purpose. Clinically it was strikingly suggestive of malignant tumor of the thigh; a typical spindle-shaped growth, which occupied the upper third of the thigh in a very large man, who did not show any particular cachexia; but the "feel" and the appearance of it, together with the history of its development and the absence of

any specific history, which was carefully searched for, suggested pretty definitely the diagnosis of sarcoma, and we advised that he have an x-ray; and as this showed the thickening we expected to see from the clinical appearances, we advised him to consult a surgeon and ascertain what was best to be done. He went to an eminent surgeon, who advised amputation at the hip joint. He said if that must be done he would go to his own school. He went to the Homeopathic Hospital and received the same advice. An exploratory operation was performed and a piece of tissue removed. Their pathologist was not prepared to express an opinion on it. A piece of this tissue was sent to the Harvard Medical School, and there the pathologist would not definitely commit himself. He asked for more of the growth. A second exploratory operation was performed, and a specimen more nearly the center of the tumor was obtained, and then both pathologists thought it was probably osteomyelitis. After a time the tumor entirely disappeared and has not recurred. This was about three years ago.

Another case that interested me a good deal, from the fact that I have heard from Dr. Coley in regard to it, is that of a young man of about eighteen, sent from the out-patient of the Massachusetts clinic to the orthopedic clinic at the Carney with diagnosis of hip-joint disease, in which we agreed, believing it was probably the acetabular type. He had no shortening; limitation of motion on abduction and extreme flexion of the limb and considerable pain, and a history extending over seven or eight months, more or less intermittent as regards the limp and pain. He had in addition to this a tumor in the left iliac region, just above Poupart's, which we supposed was an abscess coming from the acetabulum. I cut down upon that tumor, expecting to come into a pus pocket, but instead I got into a sort of currant-jelly mass which was very vascular. I put my finger in and came up against the side of the ileum, and could push through the ileum with perfect ease. It proved on examination to be round-cell sarcoma; and while he was convalescing from the operation the tumor increased in size to such an extent it was decided to send him to Coley for treatment. A few days ago I received a note saying he had commenced treatment, but that osteosarcomas in his experience were not the most suitable cases for that treatment.

DR. GARCEAU: I have had a similar case. I sent to Dr. Coley a woman about forty years of age, with osteosarcoma of the arm. She was treated about two months, came back and had the arm amputated at the hospital. The treatment did absolutely no good at all.

MEDICAL DEGREES AT HARVARD UNIVERSITY. —At the annual commencement at Harvard University, held June 26th, 116 candidates received the degree of Doctor of Medicine; of these, about thirty were graduated *cum laude*.

AMERICAN MEDICAL ASSOCIATION.

PROCEEDINGS OF THE FIFTY-SECOND ANNUAL MEETING, HELD AT ST. PAUL, MINN., JUNE 4–7, 1901.

GENERAL SESSIONS.

FIRST DAY.

THE association met in the Metropolitan Opera House, and was called to order at 10.20 A.M. by the chairman of the Committee of Arrangements, DR. JOHN F. FULTON of St. Paul. Prayer was offered by BISHOP H. B. WHIPPLE, after which Dr. Fulton introduced the HON. R. A. SMITH, Mayor of St. Paul, who delivered an address of welcome. Following the address came the introduction of the president of the association, DR. CHARLES A. L. REED of Cincinnati. On taking the chair he invited the vice-presidents and all ex-presidents of the association who were present to take seats upon the platform.

DR. PHILIP MARVEL of Atlantic City, third vice-president, took the chair, and PRESIDENT REED delivered his address.

PRESIDENT'S ADDRESS.

He referred feelingly to three of his illustrious predecessors who had been called from their worldly activities to the realms of rewards. Alfred Stille, Lewis A. Sayre and Hunter McGuire, each a former president of the association, died within a single week. Their lives were known of men, their records are ornaments of medical history, and their achievements are their eulogies.

The foreign relations of the American Medical Association were next touched upon briefly.

He passed on and considered the fiscal affairs and the *Journal*, stating that from the joint report of the treasurer and of the Board of Trustees there was a cash balance at the end of the last fiscal year of $31,004.67, being an excess of $3,696.66. He believes that the present generous policy in promoting the welfare of the *Journal* should be continued; that the dues of the association should not be decreased; and that the question of establishing and defraying the expenses of certain commissions for special scientific investigators should be taken under serious consideration. The question of tuberculosis is not yet a closed chapter. The causation of cancer is yet a sealed mystery. The problems of tenement-house reform are not yet solved. The prevention of various endemic diseases has not yet been made practicable. These are a few among the many objects of a specific character which demand and should receive the fostering care of the association.

The era of effective legislative control of medical practice came as the natural reaction from the demonstrated failure to accomplish the same result through voluntary organization, but it came as the result of the sentiment which had been propagated largely through the influence of the association.

Touching the reorganization of the association, President Reed stated that great results can be achieved only by the unification of a national profession. These could not be attained under the present organization of the association. The disproportionately rapid growth of the *Journal* as compared with that of the association could have no other significance. The weakness of the Committee on Legislation at Washington was a question neither of personnel nor of industry, but arose purely from the fact that there was no efficient organization in the rank and file of the profession by which speedy and effective influence could be brought to bear upon members and senators. The demand for more effective organization of the association had come from all over the country, and resulted in the adoption of a motion at Atlantic City authorizing the appointment of a committee of three to report a plan of reorganization at this session. Another motion was adopted authorizing the creation of a supplementary committee of one from each state and territory, entitled a Committee on Reorganization, which has been filled by appointing for the most part the retiring presidents of state societies for the current year. The Committee on Reorganization had given to the important question entrusted to it a most careful and painstaking consideration. It had laid before the association the results of its deliberations. In doing so it had emphasized the principle that this association had its origin in the organized profession of the respective states. It emphasized the fact that the delegate body should be so small that it can remain in prolonged session and give to various subjects under consideration that deliberate attention which has not been possible under the existing scheme of organization during the past forty years. It recognizes the paramount importance of the scientific feature of work by relieving the general meetings and the sections alike of the troublesome details that now consume the limited and valuable time of the sessions. It remedies the glaring and serious defects in the present constitution. It prepares the association, by perfecting the organization, to meet important and pressing questions. These considerations, together with the fact that the existing constitutional provision relative to delay of action on pending amendments has been met by the appointment a year ago of a committee for the avowed and published purpose of reorganization, and by the action of the committee in laying the results of its work before every member of the association — these considerations prompted him to advise the adoption of the proposed Constitution and By-Laws in their entirety at the present annual session of the association.

The changes which the speaker had advocated are essential for the attainment of the purposes of the association and for the fulfillment of the high destiny of the national profession. They are demanded by the changes that have taken place during the past fifty years. The legislative functions have passed from voluntary organizations to the congress and the legislatures where they belong; but it still devolves upon the profession in the organized capacity to stimulate, to restrain or otherwise to control the law-making power. The responsibility of the profession is increased rather than diminished. Science has come to have a clearer meaning. He who now proclaims a dogma cries alone in the night while the world sleeps. They who demand a creed may read its varying terms only in the progressive revelation of natural laws. Practice has changed. The depletions, the gross medications, the absurd attenuations, the ridiculous anti-mineralism have given way to a refined pharmacy and to a more rational therapy. Education implies research and discovery, and all may delve.

President Reed's peroration was as follows: "I proclaim, events proclaim the existence of a new school of medicine. It is as distinct from the schools of fifty years ago as is the Christian dispensation from its pagan antecedents. It is the product of convergent influences, of diverse antecedent origin. It acknowledges no distinctive title; it heralds no shibboleth. It is a school of human tolerance, of personal independence, of scientific honesty. It is the slave of neither prejudice nor preconception, and abandons the accepted truth of yesterday, if it only be the demonstrated error of today. It places no premium upon personal prerogatives, and extends no recognition to individual authority. It makes no proclamation of completeness, no pretention to sufficiency. It recognizes that truth is undergoing progressive revelation, not ending today, but continuing through the ages. It yields its plaudits to achievement, and recognizes that he is the greatest among men who reveals the most of truth unto men. It greets as a friend him who thinks, though he think error; for, thinking, he may think truth and thereby add to the common fund. It heeds all things, examines all things, judges all things.

"To you, the exponents of this new school, of this new generation, of this new century; to you, representatives of the democracy of science; to you, citizens of the republic of letters, I extend greetings; and here, in our parliament assembled; here, where our will is supreme, I this day invoke upon our deliberations the spirit of liberty, the spirit of courage, the spirit of progress, the spirit of truth."

The president's address was referred to the Executive Committee with instructions to report back to the association on its recommendations.

DR. J. R. PENNINGTON of Chicago made a brief speech, during which he presented and unveiled the portrait of Dr. N. S. Davis of Chicago, the veteran of the association and founder, amid a storm of applause. The portrait of Dr. Davis was accepted by the association, and thanks extended to Dr. Pennington for his presentation.

The secretary, DR. SIMMONS, read his annual report, in which he referred to the continued increase in membership and the prosperity of the association. The membership at the present time is something over 10,600, which shows an increase

over last year of between 1,500 and 1,600. The report was referred to the General Executive Committee.

DR. BULKLEY of New York read the report of the General Executive Committee, in which it was recommended that hereafter no titles of papers be printed in the program unless the required abstract is furnished and printed in connection with the same.

The next order was the joint report of the treasurer and the Board of Trustees, which was read by DR. T. J. HAPPEL of Tennessee. The report showed as profits for 1900, $13,344.91. The report was adopted as read.

The report of the Committee on National Legislation was read by DR. H. L. E. JOHNSON, chairman, which dealt with matters of interest to the profession. The report was a very lengthy one, and was referred to the General Executive Committee.

The report of the Committee on Reorganization was read by DR. J. N. MCCORMACK of Kentucky, and at its conclusion, on motion of DR. HARRIS of New York, the report was referred to a joint committee composed of the General Executive Committee and the enlarged Committee on Reorganization, with instructions to report the following morning.

SECOND DAY.

The association met at 11 A.M., with PRESIDENT REED in the chair. His Excellency, S. R. VAN SANT, Governor of Minnesota, was introduced, and welcomed the association on behalf of the State.

The joint committee, consisting of the General Executive Committee and the Committee on Reorganization, upon the report of the Committee on Reorganization, made its report, it being read by the chairman of the joint committee, DR. H. O. WALKER of Michigan.

The most important features of this report are the following:

This association shall consist of delegates, permanent members, members by invitation, honorary members and associate members. Permanent members shall consist of such members of the state societies, together with their affiliated local societies, entitled to representation in this association as shall make application for admission in writing to the treasurer, and accompany said application with a certificate of good standing signed by the president and secretary of the society of which they are members, and the annual fee. Members by invitation shall consist of distinguished physicians of foreign countries who may be invited by the officers of sections or of the association. They shall hold their connection with this association until the close of the annual session to which they are invited, and shall be entitled to participate in all of its affairs, as in the case of permanent members, but they shall not be assessed the annual dues. Honorary members shall be physicians of foreign countries who have risen to pre-eminence in the profession of medicine. Representative teachers and students of the allied sciences, not physicians, may become associate members by the vote of the House of Delegates.

The House of Delegates of the American Medical Association shall consist of (1) delegates elected by permanently organized state and territorial medical societies in affiliation with this association; (2) two delegates elected by each of the component sections of this association; (3) one delegate each from the medical departments of the U. S. Army and U. S. Navy, and one from the U. S. Marine Hospital service.

The total membership of the House of Delegates shall not exceed 150, and the delegates representing the State societies shall be apportioned among the several affiliated state and territorial medical organizations in direct ratio to their true membership.

The House of Delegates shall have authority to provide for and create such branch organizations as may be deemed essential to the promotion of the welfare of the medical profession.

The regular meetings of the association shall be held annually. The place of meeting shall be determined, with the time of meeting for each next successive year, by vote of the House of Delegates.

The officers of this association shall be a president, four vice-presidents, a secretary, a treasurer and nine trustees.

The officers of this association shall be elected by the House of Delegates. Each officer, with the exception of the secretary and the Board of Trustees, shall hold office for one year or until his successor is elected and installed. Three trustees shall be elected annually by the House of Delegates for a term of three years.

No member of the House of Delegates shall be eligible to any of the offices mentioned in the foregoing sections of this article.

The General Session shall have the right to discuss questions referred to it by the House of Delegates, and it may, by a two-thirds vote, order a general referendum on any question pending before the House of Delegates.

The House of Delegates shall, upon a two-thirds vote of its own members, or upon a two-thirds vote of the General Session, submit any question either through the *Journal* or by mail, to the general membership or final vote; and if the persons voting shall comprise a majority of the members, the majority of such votes cast shall determine the question, and shall be binding upon the House of Delegates.

The House of Delegates shall have authority to amend any article of this constitution by a three-fourths vote of all the members composing the House of Delegates; provided, that such amendment shall have been proposed in open meeting of the House of Delegates one year previous to being acted upon, shall have been published at least three times in the *Journal* during the interim, and shall have been officially transmitted to each affiliated state and territorial society for consideration at their annual meetings.

The General Session shall include all registered members and delegates, who shall have equal rights to participate in discussions and to vote upon pending questions. Each General Session shall be presided over by the president, or, in his absence or disability, by one of the vice-presidents. Before it there shall be delivered upon the opening day of each annual meeting the address of the president, whose recommendations shall thereupon go to the House of Delegates for action, and on each following session such addresses on scientific subjects as are assigned to orators selected for the purpose. It shall have power to create committees or commissions for scientific work of special interest or importance, and to receive reports of the same; provided, that any expense incurred in connection therewith by the association must first be authorized by concurrent action of the House of Delegates and the Board of Trustees.

The House of Delegates, as far as may be consistent with the articles of incorporation, shall be the legislative and fiscal body of the association. Its sessions shall be open to the members of the association; but except upon invitation of the House of Delegates, they shall have no right to participate in its proceedings. Each state and territorial society entitled to representation shall have the privilege of sending to the association one delegate for every 500 of its resident regular members, and one for any additional fraction of that number; but each affiliated state and territorial society shall be entitled to at least one delegate.

The House of Delegates once in every three years shall appoint a committee of five on reapportionment, of which the president and secretary shall be members. It shall be the duty of this committee to examine the membership lists of all the affiliated state and territorial medical societies, and to determine therefrom the number of delegates to the association to which each state or territory shall be entitled for the ensuing three years, beginning with the annual meeting next succeeding that at which the reapportionment is approved by the House of Delegates.

Members of the House of Delegates shall be elected for a term of two years, and those state and territorial societies entitled to more than one representative are requested to so arrange such election that one-half of their delegates, as near as may be, shall be elected each year.

In order that each state and territorial medical society may properly provide for a full delegate representation at each meeting of the association, it shall have the authority to elect alternates, who, upon presentation of the proper credentials, shall be empowered to serve as delegates in the absence of the regularly elected delegates. Provided, that in case of the absence of the regularly appointed delegate or alternate, then the permanent members from that affiliated society, who are present at that meeting, shall select one of their number, who shall represent that society; and provided further, that when only one permanent member is present from any society, that member shall represent that society.

No one shall serve as a member of the House of Delegates who has not been a permanent member of the American Medical Association for at least two years.

Every delegate from a state or territorial society, before being permitted to take part in the proceedings of the House of Delegates, must deposit with the secretary or other designated officer or committee, a certificate signed by the president and secretary of the state society from which he receives his authority, stating that he has been regularly and legally elected a delegate to the American Medical Association for a definitely stated term, and the delegates from the sections shall present credentials signed by the president and secretary of the section they represent. This certificate shall be subject to review by the Judicial Council, and all disputes as to credentials shall be investigated by the Judicial Council, and determined by vote of the House of Delegates.

The House of Delegates shall approve all memorials and resolutions, of whatever character, issued in the name of the American Medical Association before the same shall become effective.

The House of Delegates shall present a summary of its proceedings to the last general session of each annual meeting of the association, or it shall publish the same in a bulletin to be issued each day during the annual meeting.

A majority of the members composing the House of Delegates shall constitute a quorum for the transaction of business. All elections shall be by ballot. The election of officers shall be the first order of business of the House of Delegates after the reading of the minutes on the morning of the last day of the annual meeting. Only those in attendance at the annual meeting at which the election occurs shall be eligible for election. The officers elected at each annual meeting of the association shall be installed at the closing general session.

The Judicial Council shall be composed of nine members, three of whom shall be chosen annually by the House of Delegates, and shall serve for three years. All questions of a personal character, including complaints, protests and credentials, shall be referred at once, after the report of the Committee of Arrangements or other presentation, to the Judicial Council without discussion. The said council shall organize by choosing a president and secretary, shall keep a permanent record of its proceedings, and shall report its findings to the House of Delegates at the earliest practicable moment.

The Commitee on Medical Legislation shall consist of one delegate from each state, to be appointed annually by the president of the association. It shall be the duty of this committee to represent before Congress and elsewhere the wishes of this association in regard to pending medical and sanitary legislation. It shall be the duty of this committee to consider and act upon all proposed national, state or local legislation that in any respect bears upon the promotion and preservation of the public health, or upon the material or moral welfare of the medical profession. It shall have power to fill any vacancies that may occur in its membership, and to act *ad interim* when necessity arises.

The Committee on Legislation shall report to the House of Delegates at each annual meeting its action during the previous year, and shall recommend such action regarding pending legislation as it shall deem proper.

The Committee on Nominations shall consist of nine members, not more than one from one state or territory, selected annually by the House of Delegates. It shall be the duty of this committee, after consultations with the members of the association, to hold one or more meetings, at which the assignment of the offices of the association for each ensuing year shall be carefully considered. The committee shall then on the morning of the third day of the annual meeting report the result of its deliberations to the House of Delegates in the shape of a ticket, providing one, two or three names for each office; but not more than one candidate for each office shall be named from any one state or territory. Nothing in this section shall be construed to prevent additional nominations being made by the members of the House of Delegates.

The general sessions of the American Medical Association shall be held at 11 A.M. and 7.30 P.M. of the first day of the annual meeting, at 7.30 P.M. of the two subsequent days, and at 12 noon of the concluding day.

The various sections of the association shall hold their first session of each annual meeting at 2 P.M. of the first day, and on subsequent days of the annual meeting they shall be in session from 9 A.M. to 12 noon, and from 2.30 P.M. to 6 P.M., until their respective programs are completed, or as the sections themselves may otherwise provide.

The House of Delegates shall hold its first session of each annual meeting at 2 P.M. of the first day, and on subsequent days at such time as may be necessary to complete its business; provided, that it shall not meet at hours that will conflict with the general session of the association.

The officers of each section shall be a chairman, a secretary and an executive committee. The latter shall consist of the last three retiring chairmen. At the commencement of the afternoon session of the third day of each annual meeting, each section shall elect its own officers to serve for the ensuing year, their duties to commence with the close of the annual meeting at which they are elected, and to continue until their successors are elected and qualify. Each section shall elect annually two representatives to the House of Delegates. In each section a nominating committee of three members shall be elected by open ballot on the first day to make nominations for section officers.

After the reading of the report DR. HARRIS of New York moved that the full report of the joint Committee on Reorganization, including the revised Constitution and By-Laws, be received and adopted. After considerable discussion the report was adopted by a large majority.

DR. MCCORMACK of Kentucky then moved to reconsider the vote by which the report was adopted, and that the motion to reconsider be laid upon the table. Carried.

On motion, the Constitution and By-Laws were ordered to be printed in separate form for pocket use, and a copy distributed to every member.

DR. JOHN A. WYETH of New York was introduced, and delivered the oration on Surgery.[1]

DR. F. H. WIGGIN of New York made a verbal report in behalf of the Committee on Senn Medal, saying that the committee had received two papers during the year, neither of which was sufficiently meritorious to warrant any award.

The next order was the report of the Committee on the Rush Monument Fund, which was read by DR. HENRY D. HOLTON, showing that $11,941.88 had been contributed towards this fund. On motion, the report was received and filed.

The report of the Committee on Scientific Research was read by the secretary in the absence of Dr. Wm. H. Welch, in which the hope was expressed that the grant of $500 appropriated by the association last year would be continued, and if possible an additional $500 added to it. The report was referred to the General Executive Committee and Board of Trustees, with instructions to report back to the association.

THIRD DAY.

The association met at 11 A.M.

DR. GEORGE M. GOULD of Philadelphia offered a resolution, in which the Board of Trustees was authorized to pay the bills of expenses incurred by the Committee on Reorganization.

The president announced as the Committee on National Legislation, Drs. H. L. E. Johnson, Wm. L. Rodman and Wm. H. Welch.

DR. BULKLEY read the report of the General Executive Committee, in which it was urged that the sections on physiology and dietetics and on pathology and bacteriology be merged into one section. On motion, the report was adopted.

DR. BULKLEY also read the report of the General Executive Committee of June 6th, which related to the recommendations contained in the president's address. It was recommended by the committee that the association appoint a committee to draft appropriate resolutions commemorative of the lives and distinguished services of the recently deceased presidents of the association; that action be taken to secure suitable portraits of deceased ex-presidents; that the incorporation of the association be confirmed; that a committee of three be appointed to revise the Code of Ethics, with instructions to report at the next annual meeting; that the association pass resolutions of disapproval of the action of Congress in failing to pass the bill which provided for the proper and adequate recognition of the medical corps of the U. S. Army.

In regard to the request from the Committee on Scientific Research, the General Executive Committee recommended to the association that the $500 appropriated for this committee last year and not expended be used by that committee this year in place of the further appropriation of $500.

A communication from DR. ARTHUR MACDONALD, as to the establishment of a psycho-physical laboratory in the Department of the Interior at Washington, was received by the committee and fully discussed, and it was recommended that the following resolution be adopted with reference to the same:

Resolved, That we are in favor of the establishment of a psycho-physical laboratory in the Department of the Interior at Washington, for the practical application of physiological psychology to sociological and abnormal pathological data, especially as found in institutions for the criminal, pauper and defective classes and in hospitals, and also as may be observed in schools and other institutions.

The committee recommended that an appropriation of $500 be made for the pathological exhibit for the coming year.

On motion, the report of the General Executive Committee, with its various items, was adopted, with the exception of that section pertaining to the appointment of a committee to revise the Code of Ethics.

DR. N. S. DAVIS, JR., of Chicago, then delivered the oration on Medicine.[2]

DR. TUCKERMAN of Ohio offered an amendment to the By-Laws as follows:

SECTION 3. Committee on Legislation: The Committee on Legislation shall consist of three members appointed by the president of the association for a term of three years. One member shall be a resident of Washington, D. C., one of Baltimore, and one of Philadelphia. It shall be the duty of the committee to represent before Congress the wishes of this association regarding any proposed legislation that in any respect bears upon the promotion and preservation of the public health, or upon the material or moral welfare of the medical profession. This committee shall also invite to a conference once a year, or oftener if need be, one delegate each from the Medical Service of the U. S. Army, the U. S. Navy, and the Marine Hospital service, one from the Bureau of Animal Industry, and one from each affiliated state or territorial medical society; such conference to meet in Washington to consider questions of medical and sanitary legislation, and to report back to this association and to the several state and territorial societies. (Referred to the House of Delegates.)

Hereafter, by action of the Board of Trustees, the railroad expenses of Dr. W. B. Atkinson will be defrayed to and from each future meeting of the association.

FOURTH DAY.

The association met at 11 A.M., with the president in the chair.

DR. GEORGE M. KOBER of Washington, D. C., delivered the oration on State Medicine. He selected for his subject

THE PROGRESS AND TENDENCY OF HYGIENE AND SANITARY SCIENCE IN THE NINETEENTH CENTURY.

He said that hygiene is a department of medicine whose object is the preservation and promotion of health, and deals, therefore, with all the factors likely to influence our physical welfare. It is not an independent science, but rather the application of the teachings of physiology, chemistry, physics, meteorology, pathology, sociology, epidemiology and bacteriology to the maintenance of the health and life of individuals and

[1] See Journal, June 6, 1901, p. 541.

[2] See Journal, June 13, 1901, p. 571.

communities. The subject is very properly divided into personal and public hygiene.

The speaker then referred to the pests and unsanitary conditions of the Middle Ages. He said the nineteenth century can boast of many advances in hygiene, particularly since the European invasion of cholera in 1830. The English towns which had been visited by this disease, and those fearing similar scourges, were willing to profit by their sad experience, and freely instituted sanitary reforms in the establishment of sewers, public water supplies, sanitary homes, etc.

He passed on to the consideration of the progress of sanitation in the United States, making reference to health boards, the effects of voluntary organization on sanitation, and a national board of health. He likewise referred to national and international quarantine. He spoke of the influence of sewers and public water supplies, the influence of improved water supplies, sewage disposal and river pollution, pure food and drug legislation, laws regulating the sale of drugs and poisons, patent and proprietary medicines, industrial hygiene, sanitary dwellings for wage earners, sanitation of prisons, hospitals, sanitaria and dispensaries, school hygiene, smallpox and compulsory vaccination, venereal diseases, the management and control of infectious diseases, etc. He gave a forecast of the result of the census work upon the mortality statistics, after which he concluded his oration in the following words:

"Without wishing to underrate the brilliant achievements in surgery of the brain, stomach, intestines, liver, gall bladder and other abdominal organs, and even wounds of the human heart which have been successfully sutured in four of the nine cases reported, what after all are the ultimate benefits compared with the results obtained by improved methods in sanitation?

"Since our knowledge of the nature of infectious diseases has been more and more defined, scientific methods for their prevention have been applied. We have learned, too, that in addition to the germ there must be a suitable soil for its proliferation, and that sanitation will not only destroy the environments for its development without the body, but also place the system in the best possible condition to resist its toxic action.

"The application of this knowledge has saved millions of lives, besides an incalculable amount of human suffering and distress, not to mention the economic aspect of the question. When we remember all this, and the fact that Jenner's discovery, at the close of the last century, of a fundamental and practical method of producing artificial immunity, has been far eclipsed in the last twenty years, and that we possess today not only curative, but also protective, sera for diphtheria, erysipelas, tetanus, plague, and possibly cholera, tuberculosis, typhoid fever, pneumonia, and a number of other immunizing agents for diseases of man and lower animals, we have reason to believe that the solution of the problem of immunity is only a question of time, and we may indeed expect great possibilities in our battle against infectious diseases.

"To the solution of this problem the labors of Salmon and Smith, Sternberg, Welch, Osler, Councilman, Reed and other Americans engaged in experimental medicine have contributed their full share. Progress has crowned our past; we will not retrograde. Let our conduct raise no blush on the cheek of posterity. Let us hand in hand, with heart and mind, join in promoting the welfare of American medicine, until she has reached the proudest pinnacle in the world of science, until she has become the fountain-head of knowledge for the benefit of mankind. Then, when at last we are called upon to pass through the portals beyond, Minerva Medica, in her sweeping robes of state, will proudly but reverently present us to the Supreme Healer of the universe as types of the true physician."

The General Executive Committee recommended to the association the adoption of the following resolutions from the Section on Pathology and Bacteriology:

Whereas, Mr. John D. Rockefeller of New York, appreciating the great importance and humanitarian utility of pure scientific medical research, has recently donated the sum of $200,000 for the promotion of original investigation, and has placed the control of this sum in the hands of a committee composed of representative medical scientists, under the able chairmanship of Prof. William H. Welch of Baltimore; be it

Resolved, That the medical profession, represented by the American Medical Association, desires to express its profound appreciation of this generous gift, and of the gratifying fact that the importance and needs of scientific research in medicine are so clearly realized by the donor; also its appreciation of the wise selection of the chairman of the committee having charge of the same; be it further

Resolved, That the secretary of the American Medical Association be instructed to transmit a copy of these resolutions to Mr. Rockefeller.

On motion, the report was adopted.

The report of the Judicial Council was read by Dr. F. H. Wiggin of New York, and contained two or three references to members of the association whose names have been dropped from the roll of members for noncompliance with the By-Laws.

Dr. H. L. E. Johnson made a report on behalf of the Committee on National Legislation, which was adopted.

The committee considered the following resolution, which was proposed at a previous session by Major Louis L. Seaman, U. S. V.:

Resolved, That this body deplores the action of Congress in abolishing the army post exchange or canteen, and in the interests of discipline, morality and sanitation, recommends its re-establishment at the earliest possible date.

The committee declared the resolution to be wise and proper, and of importance to every citizen of the Republic. The resolution is the outgrowth of careful study and observation by the Medical Department of the U. S. Army, is concurred in by the commanding officers at the several posts, and is intended to correct serious abuses under the present law which result in drunken-

ness, desertion, insubordination, dishonorable discharge, crime, poverty, appalling increase in venereal disease and invalidism among the soldiers of the U. S. Army.

It was recommended that the association adopt the above resolution, and that the Congress of the United States be petitioned to repeal at the earliest moment the objectionable law which prohibits the army post exchange.

On motion, the association concurred in the report of the Committee on National Legislation, and the above resolution was adopted.

The following officers were elected for the ensuing year: President, Dr. John A. Wyeth, New York; First Vice-President, Dr. Alonzo Garcelon, Maine; Second Vice-President, Dr. A. J. Stone, Minnesota; Third Vice-President, Dr. A. F. Jonas, Nebraska; Fourth Vice-President, Dr. James A. Dibrell, Arkansas; Treasurer, Dr. Henry P. Newman, Illinois; Secretary, Dr. George H. Simmons, Illinois; Librarian, Dr. George W. Webster, Illinois; Board of Trustees, term expiring 1904: Drs. W. W. Grant, Colorado; John F. Fulton, Minnesota; T. J. Happel, Tennessee. Judicial Council: Drs. George Cook, New Hampshire; H. H. Grant, Kentucky; John B. Murphy, Illinois; Philip Marvel, New Jersey; Louis H. Taylor, Pennsylvania; John L. Dawson, South Carolina; N. Fred Essig, Washington. To deliver oration on Surgery, Dr. Harry Sherman, California. To deliver oration on Medicine, Dr. Frank Billings, Illinois. To deliver oration on State Medicine, Dr. J. M. Emmert, Iowa.

Saratoga Springs, N. Y., was selected as the place for holding the next meeting of the association; chairman of Committee of Arrangements, Dr. George F. Comstock.

Before the close of the fourth general session over 1,800 members had registered. The sections were well attended, the papers were of a high scientific order, and the discussions pointed and animated. In a word, the fifty-second annual meeting of the association was one of the most successful in its history from every standpoint.

(To be continued.)

Recent Literature.

The Medical News Pocket Formulary. Containing 1,700 prescriptions representing the latest and most approved methods of administering remedial agents. By E. QUIN THORNTON, M.D., Demonstrator of Therapeutics, Pharmacy and Materia Medica in the Jefferson Medical College, Philadelphia. Third edition. Philadelphia and New York: Lea Bros. 1901.

We have had occasion to notice this book in its earlier editions. This third edition is similar in form and contents to those already published. It is attractively bound in leather, and in connection with each prescription after the usual directions as to administration, the indications for its use are given. Such books have a definite, if somewhat limited, field of usefulness.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 27, 1901.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ATHLETIC TRAINING.

WE are again in the midst of the period of strenuous athletic life in the large colleges. Of all the contests which have now become fixtures of college life, probably none, not excepting football, are productive of so great a physical strain as the boat race about to be rowed at New London. It is, therefore, particularly fitting that we should at this time call attention to the work concluded in this number of the JOURNAL, done by Dr. E. A. Darling of Cambridge, W. O. Atwater and F. G. Benedict of Middletown, Conn., on the effects of training upon the physical conditions of the contestants.

In our issue of June 6th Darling gives the results of his investigations on the general subject of training, with particular reference to football and rowing. In the first place the fact is noted that examinations of value are made only under unusual difficulties; the men, as a rule, who are actively engaged in practice or games, are in such a state of excitement and impatience that they find it a hardship to submit to the time-taking tests which are often requisite. The paper before us is the second on the same general subject, the first having appeared in our issues of August 24 and 31, 1899, and concerns itself chiefly with the condition of the heart and kidneys. In a comparison of the effects of rowing and football, Darling finds they do not essentially differ; that in both sports the training appears to accustom the heart, kidneys and other organs to the unusual strain being put upon them in the course of the athletic season, and finally concludes that he was able to find no ill effects from the severe training nine months later.

At the instigation of the Harvard Athletic Committee through Dr. Darling, Atwater and Benedict undertook an elaborate investigation into the food and excreta of four members of the 1900 Harvard University crew during the days

immediately preceding the race. The writers of this paper call attention to the fact that such studies have hitherto not been frequently made, either in this or other countries. For the details of this exhaustive research we would refer the reader to the original papers appearing in our issues of June 20th and 27th. Like many difficult problems, however, which have as yet not been thoroughly investigated, the writers conclude their paper by urging the need of more work along the same lines. "Perhaps the most important conclusion to be derived from the experiments is that further and more detailed investigations are needed to show what diet is best for men under such severe muscular strain as that of oarsmen in training for races."

It is to this latter point that we desire particularly to refer. Valuable as the researches before us are, they are only beginnings; a very large number of examinations must be made before statistical conclusions of value may be reached. It is a peculiarly laborious piece of work on account of the conditions under which it must be undertaken, as indicated by Darling; but we are nevertheless convinced that until such studies are made, proving by accurate scientific means the danger or harmlessness of violent athletic contests, a large portion of the laity will maintain an attitude of scepticism regarding the supposed benefit to the individual contestant. We await the verdict of those capable of judging, and it is becoming clearer every year that conscientious clinical and laboratory investigation must be the final arbiter. It has long been apparent that training based on any other than physiological principles is capable of doing much harm both to the individual and to the general cause of athletic sports. We see in these studies, to which we have alluded, one of the first systematic attempts to place athletic training where it belongs,— in the hands of men qualified to determine what is actually taking place in the athlete's body, and not only what appears on the surface. A much neglected field of investigation, also, is a more detailed study of the nervous system than has hitherto been made. We are strongly inclined to think that the qualities which make the successful athlete more often lie in his mental make-up than is ordinarily supposed to be the case. This more subtle but highly important side of the general question will no doubt be considered when the last word on athletic training shall have been said.

A CENSUS OF TUBERCULOSIS.

It is said that an attempt is soon to be made in New York State to determine by as accurate a census as possible, the number of persons suffering from tuberculosis in that State. We shall await the result of the investigation with great interest, particularly since it is to be officially conducted by the State Board of Health. That such a census will be of much value as a standard by which the growth or decrease of the disease may be estimated, is self-evident; that it will be a most difficult undertaking to carry to a successful issue, is equally self-evident. Apart from the wilful tendency to deceive, which will certainly be a source of annoyance, there will undoubtedly be a large element of error among persons in whom the disease is in an incipient stage, and in whom, it may be, the diagnosis has never been made. There are many such persons in every community, who may never have consulted a physician, and of whose disease there is absolutely no official record. At best the matter is a delicate one, and one which will require much tact, as well as assiduity, to get at anything like all the facts. No doubt this has been taken into consideration, and men especially adapted for the work will be chosen. At any rate such an investigation should be productive of valuable results, however wide it may be of actual conditions. As the education of the masses goes on with regard to tuberculosis, a time will, no doubt, come when the difficulties of recording all cases will be very greatly diminished. In the meantime the undertaking of the New York Board of Health is a step in the right direction, provided it be carried out with tact and discretion. We hope that other states may see fit to follow this example, to the end that we may know how many living tuberculous persons there are, as well as how many die.

MEDICAL NOTES.

Officers of American Orthopedic Association.— The following officers of the American Orthopedic Association were elected at the last meeting held at Niagara Falls: President, H. Augustus Wilson, M.D., Philadelphia; First Vice-President, William J. Taylor, M.D., Philadelphia; Second Vice-President, G. G. Davis, M.D., Philadelphia; Secretary, John Ridlon, M.D., Chicago; Treasurer, E. G. Brackett, M.D., Boston. Philadelphia was chosen as the place for the next meeting in May, 1902.

A Bit of Journalistic Excess.— Among the news items in a recent number of one of our New York contemporaries appears the following statement under the heading "Proposed Slaughter of the Innocents": "A Denver despatch states that a prominent member of the Colorado State Medical Association introduced at the annual meeting of that society, held this

week, a proposed legislative enactment providing that, on the application of the parents, imbecile children be painlessly put to death. The proposed law is too wishy-washy. The children should be killed, whether the parents consent or not, and the latter also had better be put out of the way, lest they procreate other children of feeble intellect."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 26, 1901, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 56, scarlatina 21, measles 180, typhoid fever 7.

A CENTENARIAN. — Mrs. Mary Drew Peavey, who was one hundred and six years old May 16, died in South Boston, June 23. Mrs. Peavey was the oldest resident in the state, and had lived in three centuries. She leaves six children, more than a dozen grandchildren, forty great grandchildren, and also many descendants in the fifth generation.

SMALLPOX. — Two deaths from smallpox have occurred in Providence, R. I., since the appearance of the disease there. No more deaths are anticipated, and the disease is rapidly disappearing. Five cases of smallpox are said to have developed among the passengers of the Portuguese schooner "Zulamira," who are now under observation at Gallop's Island. No other cases are expected to develop. Cases are still appearing in various parts of the state, and about 100 cases have been reported since the middle of May.

NEW YORK.

LAXITY OF HEALTH DEPARTMENT IN BOROUGH OF QUEENS. — Dr. Obed L. Lusk, sanitary superintendent for the Borough of Queens, has been indicted by the Grand Jury of the county for alleged neglect of duty in connection with the case of John Charlton, who died of smallpox at Woodside, Long Island, on May 4th, and whose body lay unburied for fifty-two hours. The Grand Jury has also made a presentment regarding the spread of smallpox in the Astoria section of Long Island City and the lack of facilities for the handling of cases of infectious diseases. The presentment sets forth that "an alarming condition of affairs" exists in the administration of the Health Department in the Borough of Queens; stating that no dead wagon is locally attached to the sanitary bureau of the borough, and that there is no reception hospital for emergency cases.

MEDICAL SOCIETY OF THE STATE OF NEW YORK. — Dr. Henry L. Elsmer, president of the Medical Society of the State of New York, announces the appointment of his business committee for the ensuing year, consisting of Dr. Nathan Jacobson, chairman, 430 S. Salina Street, Syracuse; Dr. George Ryerson Fowler, 301 DeKalb Avenue, Brooklyn, and Dr. William C. Krauss, 371 Delaware Avenue, Buffalo. All letters and inquiries pertaining to papers and scientific communications for the semi-annual meeting to be held in New York City, Oct. 15 and 16, 1901, and the annual meeting to be held in Albany, January, 1902, should be addressed to the chairman.

INVESTIGATION OF WATER SHEDS. — At a conference held in the mayor's office on June 11th, at which Controller Coler and the chief engineers of the Finance and Water Supply Departments were present, it was decided to devote $100,000 to a preliminary investigation of water sheds, for the purpose of securing an increased supply, for which the city is to expend at least $30,000,000 during the next five years. At a meeting of the Board of Estimate and Apportionment, held June 13th, Commissioner Dalton of the Water Supply Department was authorized to acquire seventy acres of land in Forest Park, Long Island, on which to build a new distributing reservoir for the borough of Brooklyn.

BERIBERI ON A SCHOONER. — When the schooner "Alert," from Lagos, on the west coast of Africa, by way of St. Martin's, West Indies, arrived in port on June 19th, it was found that the captain was suffering from beriberi. During the voyage from Lagos to St. Martin's there were three other cases of the disease among the crew, and two of the patients died and were buried at sea. On arriving at St. Martin's the vessel was stocked with fresh water and provisions and shipped five new men; no cases developed thereafter.

SMALLPOX IN GOSHEN JAIL. — Six cases of smallpox (two of them of the confluent form) have recently developed in the jail at Goshen, N. Y. The patients were removed to the pest house at Orange Farm, and the remaining fifty-four prisoners quartered in the prison yard under a strong guard. The outbreak is believed to have originated from a prisoner who was a member of a gypsy camp.

REMOVAL OF STOMACH IN A DOG. — At the New York Veterinary Hospital an operation for complete removal of the stomach, for malignant disease, was recently performed on a fox terrier, which was a great pet in the family owning it. The animal is reported to have made an excellent recovery.

SMALLPOX AT YONKERS. — Up to two weeks ago there had been an occasional case of smallpox at Yonkers, on the Hudson, but since June 15th the disease has spread rapidly, and of late about five new cases have been reported each day.

Influenza among Horses.— Veterinary surgeons report that there is a severe outbreak of influenza among the horses of the city, and that about ten thousand animals were affected.

Miscellany.

HARVARD MEDICAL ALUMNI ASSOCIATION.

The annual meeting of the Harvard Medical Alumni Association was held at the Harvard Medical School, at 12 noon, on June 25th. There was no dinner this year, but simply an informal lunch immediately after the meeting, which was served in the medical school. The laboratories and museum were open for inspection, and the plans for new buildings were on exhibition.

The following changes in the constitution were adopted:

(1) The dinner in June shall become a triennial affair, being held in the year in which a new president of the association is chosen.

(2) Since it seems advisable to have some method whereby distant graduates may be kept informed of the sayings, writings and doings of our fellow alumni, and since the most practical plan that has yet been suggested seems to be to publish, once every three months, such items of news and notes pertaining to the medical school or graduates as may from time to time be available; to this end it would be well to appoint the president, assisted by the secretary, as a committee to collect such information and publish it. The council has already made this appointment.

It was voted that the office of "correspondent" be instituted, to the end of obtaining items of interest from various cities throughout the country, which should be published by the association.

Correspondence.

FURTHER OBSERVATIONS ON THE BROWN-TAIL MOTH.

Boston, June 24, 1901.

Mr. Editor: In the Boston Medical and Surgical Journal of June 13, 1901, there is a most interesting letter from Dr. James C. White, "Dermatitis Produced by a Caterpillar." In this letter he says there is a uniform history of the removal of caterpillars from the affected parts just preceding the eruption, and that as no such cases had previously occurred under his observation, he concludes that the larvæ must be some recently introduced species.

According to the entomologists, the brown-tail moth (euproctis chrysorrhœa) is not a recently introduced species, but has been seen in this country since 1892. The moth is of common occurrence in Europe, being found in all parts except the extreme north. During the latter part of May, 1897, these caterpillars occurred in large numbers in Somerville, in a large part of Cambridge and Everett, and part of Medford and Malden. In Somerville they occurred in especially large numbers, orchards being defoliated, the caterpillars swarming into houses, so that on Park street the washing down and sweeping out of caterpillars from the walls and piazzas of houses was of daily occurrence.

"The full-grown caterpillars are from an inch and a quarter to an inch and three-quarters in length. The head is pale brown mottled with dark brown, with reddish brown hairs scattered over the surface. The body is dark brown or black, with numerous fine, dull orange or gray spots scattered over the surface; long reddish brown, finely-barbed hairs arise from all the tubercles, and white branching hairs arise from the upper side of the lateral tubercles."[1] The hairs are very brittle and easily detached, and on coming in contact with the skin produce an intense irritation.

A number of these cases have come under my observation. The eruption is urticarial in character, appears on the face, back of neck, flexor surfaces of extremities and on the nates.

Dr. White speaks of the lesions as being arranged "in long continuous tracts, as if following the course of the creature over the skin." I cannot say that I have noticed this; the eruption can be produced by simply rubbing the hair of the caterpillar on the skin. Hairs become detached, remain on the hand; other parts of the body are rubbed by this hand, and in this manner the eruption is spread.

Truly yours,
Edith R. Meek, M.D.

JOHN W. PRAY PRIZE — A CORRECTION.

Concord, N. H., June 21, 1901.

Mr. Editor: On page 625 of your journal issued June 20, 1901, I note as follows: "The John W. Pray Prize, offered by the trustees of the New Hampshire State Hospital for original work on any branch of medicine, has been awarded to Dr. Albert E. Brownrigg for an essay on 'The Clinical Significance of the Cheyne-Stokes Symptom-Complex.'"

It is very kind of you to make mention of the fact that Dr. Brownrigg has been awarded the prize, but this prize was offered by the trustees of the New Hampshire Medical Society, and not by the trustees of the New Hampshire State Hospital. It is true that Dr. Brownrigg is at present an assistant physician at the New Hampshire State Hospital, but the New Hampshire State Hospital is not offering prizes for original work in any branch of medicine.

Allow me to say that Dr. Pray left $1,000 to the New Hampshire Medical Society, the income of which was to be devoted to offering a prize for original work in medicine, whether in the State or anywhere else. While the income upon $1,000 at the present rates is not $100 a year, yet so many years have occurred in which no paper was offered considered to be worthy of the prize, that we have in the treasury sufficient, so that for the ensuing year the trustees offer a prize of $100 for a paper in original work in any branch of medicine.

Believing that you wish to make a correct statement in any such matter, I am

Very truly yours,
G. P. Conn, M.D., *Secretary*.

LONDON CONGRESS ON TUBERCULOSIS.

Baltimore, Md., June 19, 1901.

Mr. Editor: I should like, through your journal, to call the attention of members of the profession to the important Congress on Tuberculosis, which will be held in London from July 23d to 26th. It is much to be desired that a large contingent from the United States should participate in the work. Many prominent physicians have signified their intention of joining the congress. Members of the profession wishing to do so should send their names, enclosing $5.00, to Dr. St. Clair Thomson, 20 Hanover Square, W., London.

Sincerely yours,
W. Osler, M.D.
